Acknowledgements

I am indebted to many people who have contributed to this project, in particular, my supervisor Prof. Dr. Andreas Wetzel who has been helpful in many ways from the beginning. He was one of the initiators of this research project. I would like to thank him for his careful reviews and informative discussions concerning the regional geology of the study area. I am grateful to Prof. Dr. Bernhard Fügenschuh, the co-initiator of the project, for introducing me to the subject of fission-track thermochronology and for fruitful discussions.

I would also like to thank all my friends, former and present colleagues who have helped me through the good and bad times associated with writing a PhD thesis. These include the EUCOR-URGENT team, namely Horst Dresmann, Erich Fäh, Marzio Giamboni, Kamil Ustaszewski, Pierre Dèzes, Markus Schumacher, Sebastian Hinsken, Stéphane Kock, and the other friendly people in the Bernoullianum (far too many to note by name).

A special thanks goes to Lorant Suller for his last minute review of the introductory and the conclusions parts of the thesis.

Sample preparation carried out by Laurent Cartier, Nathalie Dalcher, Johann Fleury, Jeanette Schaub, Christian Seiler and Richard Waite is greatly appreciated.

This PhD project has been supported by the Swiss National Science Foundation (Project Nos. 21-57038.99 and 20-64567.01) and carried out within the framework of the international environmental earth system dynamics research project named EUCOR-URGENT (Upper Rhine Gaben: Evolution and NeoTectonics).

This thesis is dedicated in memory of Imre Timár-Geng...

Abstract

The Upper Rhine Graben (URG) is the most discernible part of the European Cenozoic rift system. Uplifted Variscan basement is exposed in the Black Forest and the Vosges and forms the flanks of the southern URG.

The impact of the Jurassic hydrothermal activity on the interpretation of fission track (FT) data from the southern URG is elaborated by means of new zircon FT analysis on samples with known U/Pb crystallisation ages. Zircon FT central ages range from 162 Ma to 247 Ma. The analysed samples experienced substantial annealing prior to Cretaceous cooling that cannot be explained by burial alone. Instead, it is suggested that circulating hydrothermal fluids with temperatures in the order of 200-250 °C are responsible for the observed thermal anomaly, which is also evidenced by vein mineralizations.

FT ages of 28 outcrop samples collected along two E-W trending transects from the Black Forest and Vosges vary from 136 Ma to 312 Ma (zircon samples) and from 20 Ma to 83 Ma (apatite samples). Broad and/or bimodal track lengths distributions indicate a complex thermal history, which was determined by inverse modelling of apatite FT parameters and tested against the observed dataset and independent geological constraints. Cooling below 120 °C in the Early Cretaceous to Palaeogene was followed by a discrete heating event during the late Eocene and subsequent cooling to surface temperature. The modelled time-temperature paths point to a total denudation of the flanks of the URG in the range of 1.0-1.7 km for a paleogeothermal gradient of 60 °C/km, and 1.3-2.2 km for a paleogeothermal gradient of 45 °C/km since the late Eocene.

Zircon and apatite FT data from four boreholes, which penetrate the Mesozoic and pre-Mesozoic sediments and crystalline basement of northern Switzerland, are also presented. Inverse thermal modelling of the apatite FT parameters reveals the low-temperature thermal history of the crystalline basement of northern Switzerland. Moderate to rapid cooling of the samples through the apatite partial annealing zone (PAZ) at the end of the Mesozoic was followed by a distinct thermal event during the Eocene and subsequent slow cooling to present-day temperatures. The Eocene heating episode coincides with the initial rifting phases of the neighbouring URG and associated volcanic activity. Crustal-scale faults of the Permo-Carboniferous Trough of northern Switzerland could have acted as major pathways for circulating hydrothermal fluids giving rise to the observed Eocene thermal event.

I. Introduction

by Zoltan Timar-Geng

Geological background

The Upper Rhine Graben (URG) is the most conspicuous part of a major rift system that formed in central Europe since the Cenozoic (Fig. 1). It developed by passive rifting in the foreland of the Alps in response to the build-up of compressional intraplate stresses and is an example of syn-orogenic foreland splitting (Dèzes et al., 2004). Its evolution was controlled by a repeatedly changing stress field and the reactivation of pre-existing crustal discontinuities (Schumacher, 2002).

Fig. 1: The Upper Rhine Graben as part of a major Cenozoic rift system situated in the foreland of the Alps (modified after Dèzes et al., 2004). Black lines: Cenozoic fault systems, light grey: Cenozoic rift-related sedimentary basins, dark-grey: Variscan basement outcrops, black: Cenozoic volcanic fields, dashed barbed line: Alpine deformation front, BF: Black Forest, URG: Upper Rhine Graben, VG: Vosges.

In the last decades a great amount of geological and geophysical data has been collected evaluating the structure of the URG (e.g. Rothé and Sauer, 1967; Illies and Müller, 1970; Illies and Fuchs, 1974; Fuchs et al., 1987; Prodehl et al., 1995) and its Cenozoic development (Schumacher, 2002; Dèzes et al., 2004). Nucleation of initially separated basins started in the Middle to Late Eocene and these basins continuously merged to form the SSW-NNE striking

URG during Oligocene crustal extension (Schumacher, 2002). The Oligocene main rifting stage was contemporaneous to the northwestward propagation of the Alpine orogenic wedge into its foreland under conditions of increased collisional coupling (Schmid and Kissling, 2000; Ziegler et al., 2002). The late rifting stage is characterised by the main subsidence phase of the northern parts of the URG during the Early Miocene (Aquitainian) and uplift of the southern parts of the URG owing to lithospheric folding from the mid-Burdigalian onward (Schumacher, 2002; Dèzes et al., 2004). Ongoing neotectonic activity is clearly indicated by deformed Pliocene fluvial gravels (Giamboni et al., 2004a) and Quaternary terraces (Giamboni et al., 2004b) as well as by the well-known seismic activity as evidenced by strong historical earthquakes. Fault-plane solutions of recent earthquakes document ongoing sinistral strike-slip and oblique-slip movements in the URG as a result of NNW-SSE oriented compression (Werner and Franzke, 2001).

The onset of volcanic activity in the Paleocene (Keller et al., 2002) slightly pre-dates the initial graben formation and is contemporaneous to the onset of major Alpine crustal shortening (Schmid et al., 1996) and the initial phases of the magmatic activity of the North Atlantic Tertiary Province (Ziegler, 1990). The graben-related magmatism extending from the Middle Eocene to the Middle Miocene is characterised by rift-valley type alkaline basic magmas (Keller et al., 2002).

Much less is known about the post-Variscan, but pre-Tertiary geological history of the area, partly since most of the Mesozoic strata have been eroded. At the Permian/Triassic transition the Variscan mountain range was eroded forming a peneplained surface (Geyer and Gwinner, 1991). The subsequent Mesozoic era was characterised by relative tectonic inactivity, general subsidence and marine transgression. Almost uniform series of Triassic to Jurassic sediments were deposited discordantly on Permo-Carboniferous series or on the crystalline basement in a shallow epicontinental sea. Minor Jurassic reactivation of pre-existing basement structures resulted in synsedimentary deformation and small-scale thickness and facies changes (Wetzel et al., 2003). Many vein-type mineralisations of Mesozoic age (e.g., von Gehlen, 1987; Wernicke and Lippolt, 1997; see compilation in Wetzel et al., 2003), indicate a strong hydrothermal activity mainly in Jurassic times. Towards the end of the Jurassic large-scale domal uplift commenced (Illies, 1977; Geyer and Gwinner, 1991). Cretaceous to early Tertiary deposits are absent in the southern URG area. Based on interpolated isopach maps (Geyer and Gwinner, 1991) the thickness of the eroded Mesozoic sequence can be estimated amounting up to 1500 m. However, it is still a matter of debate, if deposited Cretaceous sediments were completely eroded during latest Cretaceous and Paleocene times (Ziegler, 1990) or they were never deposited (e.g. Geyer and Gwinner, 1991).

The Late Cretaceous to Tertiary cooling history of the southern URG area is roughly documented by available fission-track data (Michalski, 1987; Hurford and Carter, 1994; Wyss, 2001). They indicate slow overall cooling since the Middle Cretaceous.

Purpose and scope

In spite of the tremendous amount of geological and geophysical data currently available, there is still a gap of knowledge regarding some aspects of the regional geology of the URG. This PhD project aims at partly closing this gap by means of an extensive fission-track study. In doing so, the focus is on the uplifted flanks of the southern URG, the exhumed Variscan basement of the Black Forest and the Vosges (Fig. 1), as well as on the crystalline basement of northern Switzerland, which is the southern continuation of the Black Forest (Thury et al., 1994) presently covered by Mesozoic strata.

The gravels delivered from the Black Forest and the Vosges document the history of their uplift and erosion. For instance, Eo-Oligocene gravels deposited on alluvial fans along the southern URG locally already contain pebbles from the crystalline basement (Düringer, 1988). In contrast, the Jura-Nagelfluh, Miocene gravels shedded from the Black Forest to the south, contain Triassic pebbles in the basal parts. First crystalline pebbles occur during the Middle Miocene (Naef et al., 1985). Thus, gravel accumulations indicate strong uplift of the Black Forest-Vosges arch in the Middle Miocene. Several other gravel accumulations occupy various altitude levels above the Rhine valley reflecting the uplift history and changes of the drainage system (e.g., Naef et al., 1985; Düringer, 1988; Villinger, 1998). However, the dating of these gravels is not always exact because the biostratigraphic resolution in terrestrial deposits is low and chronometric age determinations are yet missing. Fission-track analysis, for example, could provide chronometric age data on cooling, uplift and erosion, and this is the main objective of this study.

The uplift and erosion history derived from gravel accumulations indicate that there is an evident time lag between initial graben subsidence (Late Eocene) and strong flank uplift (Middle Miocene). For other rift systems it has been shown that strong uplift of rift flanks nearly coincides with increased heat flux (e.g., Reading, 1986). This would imply that the strong thermal anomaly in the southern URG (e.g., Dèzes et al., 2004) was not related to initial graben formation. On the contrary, based on thermal modelling Villemin et al. (1986) suggested a two-phase heating, one at 40-30 Ma, contemporaneous to the initial rifting stage, and the second at around 10 Ma. The timing of the second phase is definitely uncertain because at that time the flanks had already started to rise rapidly. Such problems concerning the relation between exhumation and thermal evolution can be addressed by inverse thermal modelling of

apatite FT parameters.

Some other questions, which can possibly be addressed by an exhaustive FT study, are:

- Did the well documented Jurassic hydrothermal activity (Wetzel et al., 2003) affect the paleotemperature regime of the crystalline basement?
- Did a thermal anomaly form in relation to the rifting of the URG? If yes, when? In what dimension?
- Which were the rates of cooling, uplift and denudation? What was the timing of these processes?

Applied methods

The following section briefly reviews the methods applied in this thesis. It is meant to give the non-specialists a readily available overview about the methodologies used in order that they can follow the details without further reading. For a more detailed description of the techniques, the reader is referred to Wagner and van den Haute (1992), Andriessen (1995), Gallagher et al. (1998), Gleadow and Brown (2000) and Ketcham et al. (2000).

Fission-track dating

Fission tracks (FT) are linear trails of radiation damage in a crystal lattice produced by the spontaneous fission of ^{232}Th , ^{235}U and ^{238}U . They can be observed under an optical microscope after enlargement by a chemical etching treatment (Fig. 2). Since the fission half-lives of the first two isotopes are too long to produce a significant number of tracks, for all practical purposes all fission tracks are derived from fission of ^{238}U . The application of FT analysis as a geochronological method was introduced in the early 1960s (Price and Walker, 1962a; 1962b). The principles do not differ from those of other isotopic dating methods. The method is based upon the fission decay of an isotope (^{238}U) and the accumulation of “daughters” (the fission tracks).

An apparent age is calculated from the spontaneous track density observed on a polished surface. The uranium concentration is measured via a second set of fission tracks induced by a thermal neutron irradiation procedure. In terms of the analytical procedure for age determination the external detector method is in common usage (see e.g., Gallagher et al., 1998) and is also applied in this project. For this method, the age equation is written as:

$$t = (1/\lambda_d) \text{Ln} (\lambda_d (\rho_s / \rho_t) \rho_d \zeta g + 1),$$

where t is the age; ρ_s and ρ_i are the spontaneous and induced track densities; λ_d is the α decay constant of ^{238}U ; ρ_d is the track density in a dosimeter (a glass of known uranium concentration) monitoring the neutron flux in the reactor; g represents the geometry factor (1/2 for the external detector method); ζ is an individual calibration factor.

Fig. 2: Fission tracks in an apatite crystal (after Gleadow and Brown, 2000). a) A polished surface is cut through the mineral grain, which intersects a number of spontaneous tracks. b) After chemical etching fission tracks can be observed under an optical microscope. Confined fission tracks do not intersect the surface but have been etched where they cross another track. They are used for track length measurements.

Usually, a FT age is reported as some kind of average estimate of the individual (typically 20) single grain ages. The commonly used central age (Galbraith and Laslett, 1993) is basically the weighted mean of the log normal distribution of single grain ages. A useful graphical method for assessing the distribution of single grain ages is the radial plot (Fig. 3) introduced by Galbraith (1988, 1990). The x and y coordinates are given as:

$$x_j = 1/\sigma_j$$

$$y_j = (A_j - A_r)/\sigma_j,$$

where σ_j is the precision of the age estimate A_j , and A_r is some reference age. All data have a common normalised error. The plot also includes a circular age scale such that the age and the error of each crystal may be determined by extrapolating a line from the origin through the given data point to intercept the age scale (see Fig. 3). Thus, the more precise data plot farther from the origin allowing for the comparison of crystals of differing ages and differing precision.

Fig. 3: The radial plot as graphical method for comparing single-grain age estimates with different precisions (see text).

As a consequence of the phenomenon of annealing (e.g. Naeser, 1979) a geologic meaning can rarely be ascribed to a FT age. Over a wide temperature range, also referred to as partial annealing zone (PAZ, e.g. Wagner, 1979), fission tracks progressively shorten and at even higher temperatures disappear completely. From this it follows that FT ages are always younger than the conventional radiometric ages of the host rocks. This, at first sight, bothering characteristic of the annealing process turned out to be the key point that qualifies the FT method to become a unique tool for deciphering the thermochronology of rocks. Temperature is the most important factor that causes annealing and consequently controls the degree of track shortening. As a result, the frequency distribution of track lengths yields significant thermal history information, and in practice, from the single grain age and track length data a detailed thermal history can be constructed, rather than just dating the timing of cooling below a specific closure temperature.

Different cooling history styles give rise to different track length distributions and also varying FT ages (Fig. 4). Thus, the length distribution is essential in properly interpreting the significance of the related FT age (Gleadow and Brown, 2000).

FT dating can be applied to a number of uranium-bearing minerals, but geological materials most frequently used are the accessory minerals zircon and apatite. Because of its well established annealing kinetics (see below), mainly apatite FT length distributions are used as a diagnostic tool for thermal histories.

Fig. 4: Three different cooling history styles and associated track length distributions (after Gleadow and Brown, 2000). a) An example of rapid cooling with a narrow distribution of track lengths about a mean value of 15 μm . It results in an event age closely approximating the time of major cooling. b) Steady moderate cooling resulting in a broader, skewed length distribution. The apparent age is younger and does not relate to any particular event. c) An example of a two-stage cooling history with a typical bimodal track length distribution leading to a “mixed age without any significance in terms of the timing of a discrete geological event.

Thermal modelling

Fission tracks form and subsequently anneal as a function of time and temperature, thus the set of track lengths measured for a sample provides a continuous record of the temperatures it has experienced (Ketcham et al., 2000). Extensive studies of the annealing properties of fission tracks in apatite led to a number of numerical models, which characterise FT annealing as a function of time and temperature (e.g., Laslett et al., 1987; Carlson, 1990; Crowley et al., 1991; Laslett and Galbraith, 1996; Ketcham et al., 1999). They can be used to calculate the FT age and length distribution resulting from any given thermal history (Gleadow and Brown, 2000). The results of this forward modelling procedure can then be compared to actual observations.

In the inverse modeling approach a range of time-temperature (t-T) paths are determined that are consistent with a given set of FT data and other geological constraints (Fig. 5). This is a statistical process involving the generation of a large number of candidate t-T paths, evaluation of the goodness of fit between model predictions and the measured data, and a method for searching among the various acceptable t-T paths for the best-fitting solutions (Ketcham et al., 2000). The basic modelling approach is to enter independent constraints on the thermal history, i.e. t-T constraints through which the thermal history must pass, and have the numerical model find what thermal histories both satisfy the constraints and predict FT parameters that adequately fit the measured data.

Fig. 5: Thermal modelling results as generated by the computer program AFTSolve (Ketcham et al., 2000). Confidence envelopes bound all "acceptable" (light grey) and "good" (dark grey) fits. K-S test: Kolmogorov-Smirnov test evaluating the degree of fit between FT length distributions. Age GOF: FT age goodness-of-fit test. For more details on the statistical procedures, see Ketcham et al. (2000).

It should be noted, that regardless of the annealing model and software used, a wider array of possible modelling results exists than is found by any model runs. Therefore,

independent constraints and a thorough geological understanding of the studied region are crucial for correctly interpreting the modelling results.

Organization of the thesis

This is a cumulative thesis, consisting of an introduction (Chapter I), three independent published papers (Chapters II-IV), and a summary of general conclusions (Chapter V). Chapter II focuses on the impact of the Jurassic hydrothermal activity on the interpretation of zircon FT data from the southern URG. It quantifies the timing of the observed thermal anomaly and the minimum temperature of the circulating hydrothermal fluids. In Chapter III the low-temperature thermal history of the flanks of the southern URG is determined by inverse thermal modelling of FT parameters. This article also attempts at giving an estimation of the total amount of denudation from the flanks of the URG since the Upper Eocene. Chapter IV presents the post-Variscan thermal history of the crystalline basement of northern Switzerland.

An appendix includes the raw FT data. With their help all FT analysis and thermal modelling results presented in the thesis can be reproduced.

Due to this organization a certain amount of repetition could not be avoided, even though each one of the individual units focused either on a different aspect of the thermal evolution or on a different part of the southern URG area. The contribution of the coauthors (Chapters II-IV) was restricted to careful reviews of earlier versions of the manuscripts and stimulating discussions of the results.

The impact of the Jurassic hydrothermal activity on zircon fission track data from the southern Upper Rhine Graben area

Zoltan Timar-Geng¹, Bernhard Fügenschuh¹, Urs Schaltegger² and Andreas Wetzels¹*

Abstract

The influence of the Jurassic hydrothermal activity on the interpretation of fission track (FT) data from the southern Upper Rhine Graben (URG) is elaborated by means of new zircon FT analyses on samples with known U/Pb crystallisation ages. Zircon FT central ages display a wide spectrum from 162 ± 14 Ma to 247 ± 22 Ma. The combination of the U/Pb ages, independent geologic evidence (such as Mesozoic subsidence history, timing of hydrothermal activity, and apatite FT ages) and the zircon FT data unambiguously indicate a Jurassic thermal overprint in the investigated area. It is suggested that circulating hydrothermal fluids with temperatures in the order of 200–250 °C were responsible for the observed thermal anomaly.

The Jurassic hydrothermal fluid migration appears to have been related to a heating event on a regional scale. Inferences from FT analyses related to burial or denudation history have to take into account how such hydrothermal events affect the FT system, including a changing geothermal gradient with time.

Keywords: Black Forest, Vosges, zircon, fission track, partial annealing zone, thermal history.

Introduction

The Upper Rhine Graben (URG) is the most perceptible part of the European Cenozoic rift system (Fig. 1) that extends from the North Sea into the western Mediterranean. Exhumed Variscan basement is exposed in the Black Forest and the Vosges and forms the flanks of the southern URG.

The emplacement age of volcanic and plutonic rocks in the Vosges was found to be very consistent in the range of 345 to 340 Ma (Schaltegger et al., 1996). In the Central Vosges the granulite-facies metamorphism was dated at about 335 Ma and amphibolite-facies retrograde overprint at about 328 Ma (Schaltegger et al., 1999). The analysed granites and rhyolites in the southern Black Forest yielded emplacement ages of 340 to 332 Ma (Schaltegger, 2000). Late Palaeozoic erosion affected the area, with the notable exception of some intramontane basins (e.g. Diebold, 1989). Thus, the base of the Mesozoic strata rests on Variscan crystalline basement.

While the URG and its Cenozoic evolution have been thoroughly studied in the past decades (e.g. Rothé and Sauer, 1967; Illies and Müller, 1970; Illies and Fuchs, 1974; Fuchs et al., 1987; Pro-

dehl et al., 1995; Schumacher, 2002), much less is known about the Mesozoic geological history of the area. This is partly due to the fact that most of the Mesozoic strata have been eroded. After Variscan folding, uplift and subsequent denudation, the URG area became part of the central European intracontinental basin, which developed since the Permo-Triassic until the end of the Jurassic (Geyer and Gwinner, 1991). Based on interpolated isopach maps (Geyer and Gwinner, 1991) the thickness of the eroded Mesozoic deposits in the URG area is estimated to be at most 1500 m. Towards the end of the Jurassic (e.g. Geyer and Gwinner, 1991) or later (Ziegler, 1990) the URG area was uplifted above sea level.

In the outcrops of crystalline basement many vein-type mineralisations of Mesozoic age are preserved (e.g. von Gehlen, 1987; Wernicke and Lippolt, 1997; see compilation by Wetzels et al., 2003), evidencing a strong hydrothermal activity mainly in Jurassic times.

In the present study we apply zircon fission track (FT) analysis to basement samples from the Vosges and Black Forest, which were already dated by the U/Pb method (Schaltegger et al., 1996, 1999; Schaltegger, 2000) and thus, provide additional information on the thermal history of the

rocks. Available apatite FT data range from ~37 Ma to ~75 Ma in the Vosges, and ~29 Ma to ~107 Ma in the Black Forest (Michalski, 1987; Hurford and Carter, 1994; Wyss, 2001). Published uplift rates of the Black Forest (Wagner *et al.*, 1989) are inferred from apatite FT data using rather simple assumptions about the paleotemperature field, i.e. constant geothermal gradients. Such an approach may lead to erroneous conclusions about the thermotectonic evolution, if convective heat transport mechanisms changed the temperature field with time. In this study we will focus on the influence of the Jurassic hydrothermal activity on the interpretation of zircon FT data from the Black Forest and Vosges.

Jurassic hydrothermal activity

In the study area, i.e. the Variscan basement of the Vosges and Black Forest, several prominent hydrothermal events have been reported previously (e.g., Wernicke and Lippolt, 1993; Lippolt and

Kirsch, 1994; see compilation by Wetzel *et al.*, 2003). Two fossil geothermal systems were identified in the intramontane troughs of Baden-Baden, northern Black Forest (Zuther and Brockamp, 1988; Brockamp *et al.*, 1994) and Offenburg, central Black Forest (Brockamp *et al.*, 2003). For these two well documented cases the observed thermal anomaly is clearly related to fault zones and heating effects can be studied in the adjacent rocks (e.g., Brockamp and Zuther, 1983; Brockamp *et al.*, 1987, 1994; Tapfer, 1987; Zuther and Brockamp, 1988; Meyer *et al.*, 2000; Brockamp *et al.*, 2003). In the Baden-Baden trough, Upper Carboniferous, Lower Permian and Triassic sediments were hydrothermally altered during the Jurassic (Zuther and Brockamp, 1988). Vitrinite data indicate that the hydrothermal fluids reached temperatures between 240 and 290 °C (Brockamp and Zuther, 1983). This fossil geothermal system is documented by three distinct alteration zones, including from center to margin, sericitisation, albitisation and weak alteration (Zuther and Brockamp, 1988). K/Ar data on authigenic il-

lites and hydrothermally altered detrital micas reveal two major episodes of fluid migration (Brockamp et al., 1994). The first episode occurred during the Jurassic (150 Ma) and extensively altered the sediments near the fault system of Gernsbach, which is located between the Saxothuringian and Moldanubian zone. The second hydrothermal phase occurred during the Cretaceous (100 Ma) and formed the fluorite-quartz vein-type mineralisation of Käfersteige (Brockamp et al., 1994). In the Offenburg trough, central Black Forest (Brockamp et al., 2003), K/Ar data on sericites point to hydrothermal activity also during the Jurassic (145 Ma). Oxygen isotope data for sericite, sericite composition and vitrinite reflectance investigations indicate hydrothermal fluid temperatures between 150 to 210 °C (Brockamp et al., 2003).

Multiple hydrothermal activities mainly during the Jurassic can be traced around the Paleotlantic all over western Europe (e.g., Mitchell and Halliday, 1976) suggesting fluid circulation on a wide regional scale. With fluid temperatures in excess of 200 °C at shallow crustal levels, and expecting a pervasive heating of the basement due to continent-wide rifting events during the opening of the North-Atlantic, these hydrothermal events should have substantially altered the paleotemperature field. Thus, interpretation of FT data assuming a constant geothermal gradient leads inevitably to erroneous results.

Fission track analysis

Zircon FT thermochronology provides insight into the low temperature thermal history of rocks between ~300 °C and ~180 °C, covering the gap between the K/Ar mica and apatite FT dating. Zircon FT analyses were carried out on 21 samples, 14 from the Vosges and 7 from the Black Forest (Figs. 2, 3). For details on lithology and localities the reader is referred to Schaltegger (2000) and Schaltegger et al. (1996, 1999).

Analytical procedure

Mineral separation and sample preparation followed standard procedures. After mounting in PFA® Teflon, zircon grains were polished and etched in a KOH–NaOH eutectic melt at 220 °C for variable times up to 12 h depending on track revelation. Thermal neutron irradiation was carried out at the Australian Nuclear Science and Technology Organisation (ANSTO) facility, Lucas Heights, Australia. All samples were analysed using the external detector method (Naeser, 1976;

Gleadow, 1981). Detector micas were etched for 40 minutes in 40% HF at room temperature. Track counting was performed using an optical microscope (“Axioscope” by Zeiss) with the aid of a computer driven stage (Dumitru, 1993). Magnification was 2500 × using an oil immersion objective. Ages were determined using the zeta approach (Hurford and Green, 1982, 1983) with a zeta value of 113.49 ± 1.80 (Fish Canyon Tuff, CN1). Data processing, error calculation and graphical presentation was performed using free-ware provided by I. Dunkl (2002). All ages are central ages (Galbraith and Laslett, 1993) and errors are quoted at the 1 σ confidence level. Results are given in Table 1 according to the I.U.G.S. recommendations (Hurford, 1990).

Zircon fission track partial annealing zone

In a wide temperature range, known as partial annealing zone (PAZ; Wagner and van den Haute, 1992), fission tracks gradually shorten and eventually disappear completely in response to elevated temperatures over geological timescales.

In case of the apatite FT system the temperature range of the PAZ (~120–60 °C) and the annealing kinetics are well established (e.g. Green et al., 1986; Laslett et al., 1987; Carlson et al., 1999; Donelick et al., 1999; Ketcham et al., 1999). The temperature interval over which FT partial annealing in zircon occurs is, however, still a matter of debate. Early annealing experiments performed on zircon suggest high closure temperatures (exceeding 300 °C) (Fleischer et al., 1965; Krishnaswami et al., 1974; Carpena, 1992) and/or a very broad temperature interval of the PAZ ranging from ~170 to 390 °C (Yamada et al., 1995). Geological constraints on the stability of fission tracks in zircon generally do not confirm such high values. For rocks with a well-established cooling history it is possible to assign a “closure temperature” of the zircon FT system by interpolating the determined FT age. Such calibration yielded effective closure temperatures of ~175 °C (Harrison et al., 1979) and 240 ± 50 °C (Hurford, 1986) for the zircon FT system. Zaun and Wagner (1985) estimated the effective closure temperature to be 210 ± 20 °C on the basis of analysed zircon samples from a borehole section. They interpreted the age reduction with depth as a fossil PAZ. Deep borehole samples from the Vienna Basin revealed no partial annealing in zircons for temperatures up to ~200 °C and a heating duration of the order of 5–10 Ma (Tagami et al., 1996). This information, coupled with a relatively narrow temperature interval of ~230 to ~330 °C for the PAZ (Tagami and Shimada, 1996; Tagami et

al., 1998), implies an effective closure temperature of 280 ± 50 °C. The latter value would in principle validate the results of laboratory extrapolations (Yamada et al., 1995) to geological time-scales.

However, experience shows that some kinetic properties of the grains/samples in combination with different thermal histories (fast versus slow cooling) lead to distinct annealing characteristics and hence, give rise to the observed range in (zircon) FT closure temperatures.

In the case of apatite, for example, there is a clear correlation between chemistry and single-grain ages (Green et al., 1986; O'Sullivan and Parrish, 1995) and the higher resistivity of chlorine-rich apatites with respect to fluor-apatites is well known. A similar relationship seemingly exists between the density of accumulated α -recoil tracks (the damage produced by α -decay events)

and the single-grain age of zircons (Kasuya and Naeser, 1988; Yamada et al., 1995). This relationship, however, strongly depends on the thermal history of the investigated rocks as the thermal stability of zircon decreases with increasing α damage (Kasuya and Naeser, 1988). Based on field and laboratory observations Rahn (2001) proposed an α damage partial annealing zone at higher temperatures than that for the fission tracks in zircons. If a sample cools rapidly through the α damage PAZ and subsequently through the zircon FT PAZ, no α damage will be present and thus the annealing of newly forming fission tracks will occur within a pristine lattice. Conversely, samples, which are heated and enter the zircon FT PAZ from the lower temperature side, will have accumulated α damage over time and the level of this damage will influence the rate of FT annealing (Rahn et al., 2004).

It seems difficult to define a generally applicable zircon FT PAZ because of the manifold dependencies of the annealing characteristics of different samples. As pointed out by Rahn (2001), it is often more appropriate to rely on a “single-grain partial annealing zone” and to define a “sample partial annealing zone” as the integral of partial annealing zones of all grains within a sample. In particular for the determination of the lower temperature boundary of the zircon FT PAZ, it is crucial to independently know the style of the thermal history, i.e. to know whether or not the sample entered the PAZ from the low temperature side. The amount of accumulated radiation damage has important implications for the temperature interval, at which zircon FT annealing occurs.

A compilation of annealing models and geologic constraints (Fig. 4) reveals a broad range for the zircon FT PAZ and reflects its various dependencies on some key parameters such as the cooling rate, the amount of accumulated α damage and consequently the style of the cooling history.

Single-grain age distributions

χ^2 statistics (Table 1) indicate that all grains analysed for individual samples belong to a single age population (Green, 1981). Thus, taking a probabil-

ity of less than 5% as evidence for a mixed age population, the observed large spread in single-grain ages does not represent real differences between the apparent ages because $P(\chi^2)$ values are consistently higher than 5%. The absence of extra-Poissonian variation is also indicated by the radial plots, since all data points scatter within $\pm 2\sigma$ around the mean. So, from a formal statistical point of view, there is no need to further analyse the single-grain age variation. On the other hand, it has to be noted that the error on all crystals is notably high because of the low number of counted tracks. Thus, the χ^2 test may have lacked power to detect any extra-Poissonian variation due to the high standard error of the single-grain age estimates and the low number of random samples (generally 20 grains). This can be illustrated assuming we would obtain the same ratio of induced and spontaneous tracks on crystal surfaces ten times greater than the observed ones (Fig. 5). If we calculate the statistics with these new values, the χ^2 test would fail and we could deal with multiple age populations. Once again, we are fully aware that a statistically founded evaluation of the single-grain age data is not possible. However, after careful consideration of the raw data and relying on our understanding of the underlying processes, we conclude that the observed spread in single-grain ages shows extra-Poissonian variation due to different annealing

Fig. 4 Constraints on the zircon FT PAZ (modified after Rahn *et al.*, 2004). Light grey: range of the PAZ constrained by fanning annealing models. Dark grey: PAZ derived from geologic evidence. Highest temperatures for the upper (high-temperature) boundary of the PAZ are calculated on the basis of annealing experiments with α damage-free zircon samples (Rahn *et al.*, 2004). Lowest temperatures are derived from geologic examples with long-duration heating episodes (e.g., Zaun and Wagner, 1985).

Fig. 5 (a) Radial plot and age-spectrum as probability-density diagram for one sample (SU-95-17) from the Vosges. All single-grain ages plot within $\pm 2\sigma$ around the mean. (b) Hypothetical plots of the same sample simulating data on ten times greater crystal surfaces ($N_s \times 10$ and $N_i \times 10$, the N_s/N_i ratio remaining the same). Under this assumption, the single-grain ages show extra-Poissonian variation.

kinetics of the individual grains. This is further evidenced by the fact that none of the samples experienced fast cooling rates and for this reason the individual grains could accumulate different amounts of α damage causing varying annealing properties of the respective grains (Rahn et al., 2004). Therefore, the following discussion is based on this assumption.

Analyses of single-grain age distributions of detrital zircons have been proven to provide accurate results in exhumation and provenance studies (e.g., Spiegel et al., 2000; Bernet et al., 2001; Stewart and Brandon, 2004). The underlying concept is that recycled sediments may contain zircons derived from various source regions with different thermal histories, thus displaying more than one population of zircon FT ages. However,

a large spread in single-grain age distributions may also occur due to different track retentivity of the individual grains within one sample, for example owing to variable amounts of accumulated α damage (Kasuya and Naeser, 1988). Over the last decades, several attempts have been made to extract thermochronological information from FT single-grain age data from previously fully or partially annealed samples, based on differential annealing of individual grains (e.g. Green, 1989; Sobel and Dumitru, 1997; Brandon et al., 1998; Fügenschuh and Schmid, 2003). A useful concept is the interpretation of the fraction of zircons with the youngest single-grain ages as those with the lowest thermal stability because they will be the last to close on a cooling path (Brandon et al., 1998). The inference is that the youngest single-

grain age represents a maximum age for the date when the sample finally left the PAZ (Fig. 6).

Results

In the Vosges, zircon FT central ages range between 164 ± 15 Ma and 247 ± 22 Ma (Fig. 2, Table 1). No regional trend can be observed.

Very similar results were obtained for the southern Black Forest with zircon FT central ages ranging between 162 ± 14 Ma and 224 ± 22 Ma (Fig. 3, Table 1), with a weak tendency for older ages to be found more to the west of the Black Forest.

Neither for the Black Forest nor for the Vosges a correlation of FT age with altitude could be observed (Fig. 7). An altitude dependence of increasing ages with elevation was not even observed for samples, derived from coherent fault bounded blocks.

Radial plots (Galbraith, 1988, 1990) of analysed samples reveal broad single-grain age variations within individual samples (Figs. 2, 3), however, all samples passed the χ^2 -test (Green, 1981).

Therefore, from a statistical point of view all samples are characterised by only one grain population. The single-grain ages of each sample, as depicted in the radial plots (Figs. 2, 3), display a broad range from ~ 340 Ma to ~ 100 Ma.

All single-grain ages from the Black Forest and Vosges together with the superimposed central ages (Fig. 8) reveal a maximum at ~ 190 Ma in the Vosges and at ~ 170 Ma in the Black Forest.

Discussion

Pre-Tertiary thermal event in the URG area

The samples from the Black Forest and Vosges have experienced substantial annealing, indicated by the reduced zircon FT central ages with respect to the emplacement ages. Based on independent geological evidence the post-Variscan thermotectonic evolution can be roughly reconstructed. It started with the emplacement of the magmatic rocks at the time, given by the U/Pb ages. Of special interest are samples from volcanic rocks and samples taken close to the base of the

Fig. 6 Thermal history scenario with a thermal peak situated within the PAZ together with a possible single-grain age distribution (after Fügenschuh and Schmid, 2003). The youngest single-grain age corresponds to the time (t_{ic}) when the sample cools through the lower limit of the zircon PAZ. For further explanations, see text.

Fig. 7 Age-elevation profiles from the Vosges and the Black Forest. Four highlighted samples from the Vosges (SU 95-18, SU 95-19, SU 96-5 and SU 97-2) indicate that even samples from an apparently homogeneous block do not reveal correlation between the two parameters.

Triassic cover series (e.g. SU-96-6 from the Black Forest). In addition, the Permo-Triassic paleosurface is partly preserved in the Black Forest and has been mapped in the past decades (e.g. Paul, 1955; Wimmenauer and Schreiner, 1990). Thus it is possible to reliably estimate the thickness of the eroded pre-Mesozoic crystalline rocks to be 200 to 600 m, depending on the present elevation of the samples. For the Vosges a similar amount of eroded material is assumed. From the available apatite FT data (Michalski, 1987; Hurford and Carter, 1994; Wyss, 2001), and the youngest zircon FT single-grain ages it is clear that all samples had already cooled to temperatures below the zircon PAZ at ~100 Ma. Thus, partial annealing of the zircons must have occurred between the U/Pb ages of 330 Ma and 100 Ma.

Taking the estimated thickness of the Mesozoic sequence into account (~1500 m), the samples have experienced maximum burial of ≤ 2100 m (thickness of the Mesozoic sediments + ≤ 600 m eroded crystalline basement) at the end of the Mesozoic subsidence phase. Thus, elevated temperatures needed for the observed annealing due to burial alone are impossible to reconcile with the known geology of the region. Interpretation of the zircon FT data using a paleogeothermal gradient of 30 °C/km would suggest a burial of the present earth's surface of 5–6 km. Instead, the Jurassic hydrothermal fluid migration is suggested to have led to the increased paleotemperatures. The consequence of this convective heat transport seems to have been a heating event of regional extent because its effect can be detected in each of the samples.

Fig. 8 Frequency distribution of central ages (light grey) and single-grain ages (dark grey) for the whole Vosges and Black Forest regions. Black bars represent the U/Pb ages of the same samples.

Since the samples entered the zircon FT PAZ from the lower temperature boundary after a prolonged period at lower temperatures, a substantial amount of α damage could be accumulated causing a decreased thermal stability of the zircon fission tracks. Thus, rather moderate temperatures of 200–250 °C would have been sufficient to cause the observed thermal anomaly. Fluid temperatures of this magnitude were reported by Brockamp and Zuther (1983) for the Baden-Baden trough based on vitrinite data. This thermal input is furthermore evidenced by paleomagnetic data from the Southern Vosges (Edel, 1997), documenting post-Permian thermal overprinting.

Zircon FT central ages and single-grain ages from the study area cluster around 190 Ma (Fig. 8). This coincides with the main hydrothermal phase (e.g. Brockamp et al., 1987, 1994; Wernicke and Lippolt, 1993; Lippolt and Kirsch, 1994; see compilation by Wetzel et al., 2003) and one of the most conspicuous subsidence pulses in the investigated area (Wetzel et al., 2003). Furthermore K–Ar data from authigenic illites in sandstones (Schaltegger et al., 1995) and from ore deposits (e.g. Bonhomme et al., 1983) in Europe scatter

around 180–190 Ma. Obviously this was a time period of enhanced fluid flow (illite growth; Schaltegger et al., 1995).

Conclusions

The analysed samples experienced substantial annealing of fission tracks in zircon prior to Cretaceous cooling. Temperatures needed to allow for the observed annealing cannot be due to burial alone.

Instead, annealing is suggested to be related to a Jurassic thermal pulse, as evidenced by vein mineralisations. A thermal event is independently supported by the well-established hydrothermal activity in the investigated area, although further research is needed to determine the extent of this overprint. However, based on the present study the heating event caused by the Jurassic hydrothermal fluid migration seems to have influenced the upper crust of the southern URG area on a regional scale.

Due to the fact that samples entered the PAZ from the lower temperature boundary and were

only partially annealed, it can be assumed that a high density of α damage substantially lowered the thermal stability of the zircon fission tracks. Consequently, fluid temperatures in the order of 200–250 °C, as reported for the Jurassic hydrothermal activity in the Baden-Baden and Offenburg troughs (Brockamp and Zuther, 1983; Brockamp et al., 2003), could have been sufficient to substantially alter the palaeotemperature field in the southern URG area.

The impact of the Jurassic hydrothermal activity has important consequences on the interpretation of FT data from the URG area. Analysis of FT data using simple assumptions such as a constant paleogeothermal gradient leads inevitably to erroneous conclusions. The same is also true for the apatite FT system, especially considering that it is even more temperature-sensitive than the zircon FT system. Fluid circulation associated to Cenozoic rifting may have played a substantial role also with respect to apatite FT data. In the light of these results the interpretation of available apatite FT ages from the Black Forest as cooling ages (Michalski, 1987) is also arguable and corresponding uplift rates may have to be revised.

Acknowledgements

This work has been supported by the Swiss National Science Foundation (Project Nos. 21-57038.99 and 20-64567.01) and is a contribution to the EUCOR-URGENT project. Discussions with B. Schneider and F. Weiss about the statistical treatment of our data greatly improved the manuscript. Critical reviews by I. Dunkl, A. Hurford and an anonymous reviewer are gratefully acknowledged.

Abstract The Upper Rhine Graben (URG) is the most perceptible part of the European Cenozoic Rift System. Uplifted Variscan basement of the Black Forest and the Vosges forms the flanks of the southern part of the graben. Apatite and zircon fission-track (FT) analyses indicate a complex low-temperature thermal history of the basement that was deciphered by inverse modelling of FT parameters. The models were tested against the observed data and independent geological constraints. The zircon FT ages of 28 outcrop samples taken along an E–W trending transect across the Black Forest and the Vosges range from 136 to 312 Ma, the apatite FT ages from 20 to 83 Ma. The frequency distributions of confined track lengths are broad and often bimodal in shape indicating a complex thermal history. Cooling below 120°C in the Early Cretaceous to Palaeogene was followed by a discrete heating episode during the late Eocene and subsequent cooling to surface temperature. The modelled time–temperature (t – T) paths point to a total denudation of the flanks of URG in the range of 1.0–1.7 km for a paleogeothermal gradient of 60°C/km, and 1.3–2.2 km for a paleogeothermal gradient of 45°C/km since the late Eocene.

Keywords Upper Rhine Graben · Black Forest · Vosges · Fission-track · Low-temperature thermal history

Introduction

The Upper Rhine Graben (URG) forms part of a complex Cenozoic rift system that extends over a distance of more than 1,000 km from the North Sea to the western Mediterranean (Fig. 1). The N–NE trending southern branch of the URG is flanked by uplifted Variscan basement, exposed in the Black Forest and Vosges, and limited to the south by the Swiss Jura Mountains.

In the last decades, a large amount of geological and geophysical data has been collected by evaluating the structure of the URG (e.g. Rothé and Sauer 1967; Illies and Müller 1970; Illies and Fuchs 1974; Fuchs et al. 1987; Prodehl et al. 1995) and its Cenozoic evolution (e.g. Schumacher 2002; Dèzes et al. 2004). The URG developed in the foreland of the Alps by passive rifting in response to the elevated collision-related compressional intraplate stresses (Dèzes et al. 2004). Thus, the Cenozoic uplift and exhumation history of the Black Forest and Vosges may reflect changes in the interplay between the Alpine orogenic wedge and its foreland (Schumacher 2002) as well as onset of plume-type upwelling of the sub-lithospheric mantle and thermal weakening of the foreland lithosphere (Dèzes et al. 2004). In this context, it is of particular interest to closely constrain the low-temperature thermochronology of the strongly uplifted flanks of the southern URG as this especially may reveal the timing and magnitude of distinct heating and cooling events. Furthermore, there are still some ambiguities concerning the overall picture. For example, the time lag between Late Eocene initial graben formation and Middle to Late Miocene flank uplift suggests that these two phases are not closely related. In addition, the amount of rift flank exhumation in the southern part significantly exceeds that in the north.

Fission-track (FT) analysis is a suitable method, particularly to reconstruct the low-temperature thermal history of the uppermost parts of the crust. It has

already been successfully applied to continental extension zones (e.g. Foster et al. 1993; Foster and Gleadow 1996; Foster and Raza 2002). Existing apatite FT data (Michalski 1987; Wagner 1990; Hurford and Carter 1994; Wyss 2001) from the southern URG area roughly document the Late Cretaceous to Tertiary cooling history of the Black Forest and Vosges. These apatite FT ages cluster around 80–100, 55–70 and 30–40 Ma and indicate slow overall cooling since the Middle Cretaceous. These early studies revealed pronounced block faulting and an increased paleogeothermal gradient, which have been related to the formation of the URG (Michalski 1987; Wagner et al. 1989; Wagner 1990). However, to provide a more comprehensive analysis, it is desirable to include the track length distributions, which have a direct record of the temperatures experienced since accumulation of the tracks. Together with the FT age, they can be used to reconstruct quantitatively the thermal history.

It is the purpose of the present investigation to elucidate the low-temperature thermal history of the flanks of the southern URG. Based on new zircon and apatite FT data from basement rocks sampled along two E–W trending transects in the Black Forest and the Vosges (Fig. 2), the thermal history was evaluated by an inverse modelling procedure.

Post-Variscan evolution

After the late Variscan consolidation of the crust, the mountain range in the today's area of the southern URG was eroded forming a peneplain at the Permian/Triassic transition (Geyer and Gwinner 1991). Compared to the late Paleozoic, the Mesozoic was a period of relative tectonic inactivity characterised by subsidence and marine transgression. A series of up to 1,500 m well-stratified Triassic to Jurassic sediments accumulated on Permo-Carboniferous sedimentary rocks or on the crystalline basement (Geyer and Gwinner 1991). Only minor Jurassic reactivation of pre-existing basement structures led to synsedimentary deformation and some variations in thickness and facies (Wetzel et al. 2003). Contemporaneous substantial hydrothermal activity is evidenced by many vein-type mineralizations of Mesozoic age (e.g. von Gehlen 1987; Wernicke and Lippolt 1997; see compilation by Wetzel et al. 2003). Zircon FT data indicate that circulating hydrothermal fluids with temperatures in the order of 200–250°C significantly altered the paleotemperature field in the upper crust during Mesozoic times (Timar-Geng et al. 2004). In the southern URG area large-scale domal uplift commenced towards the end of the Jurassic (Illies 1977; Geyer and Gwinner 1991). Cre-

taceous to Palaeogene deposits are absent in this area. However, it is still a matter of debate, if Cretaceous sediments were completely eroded during latest Cretaceous and Paleocene times (Ziegler 1990) or if they were never deposited (e.g. Geyer and Gwinner 1991).

The Cenozoic evolution of the southern URG area is characterised by renewed tectonic activity reflecting the interaction of the Alpine orogen with its foreland (Dèzes et al. 2004). Rifting and subsidence of the URG started with the nucleation of Middle to Late Eocene local basins,

which further evolved and became connected under repeatedly changing stress fields, and remained active until the present (Schumacher 2002). Middle Miocene large-scale uplift of the Black Forest and the Vosges due to lithospheric folding was controlled by NW-directed compressional stresses built up in the Alpine foreland (Dèzes et al. 2004). The volcanic activity started slightly before the initial graben formation, but remained active until Miocene times (Keller et al. 2002). The associated mantle upwelling system beneath the Alpine foreland caused thermal weakening of the lithosphere (Ziegler et al. 1995).

Neotectonic activity is clearly shown by deformed Pliocene fluvial gravels (Giamboni et al. 2004), and the elevated seismic activity as evident by strong historical earthquakes in the URG area. Fault-plane solutions of recent earthquakes document ongoing sinistral strike- and oblique-slip movements in the URG as a result of NNW–SSE oriented compression (Werner and Franzke 2001).

Fission-track thermochronology

The FT dating is a radiometric dating method to determine a FT age of uranium bearing minerals like zircon and apatite (for a detailed overview see, e.g.

Gallagher et al. 1998; Gleadow and Brown 2000). The spontaneous fission of ^{238}U leaves a trail of damage in the crystal lattice (Price and Walker 1962a, b). From the number of tracks formed since the crystal for the last time cooled below the track retention temperature, a FT age can be calculated. Because of a process called annealing (e.g. Naeser 1979), a geologic meaning can rarely be ascribed to such an age. In a wide temperature range, referred to as partial annealing zone (PAZ, e.g. Wagner 1979), fission tracks gradually shorten and at even higher temperatures disappear completely over geological time. As a result, FT ages are often younger than the conventional (U-Pb and K-Ar) radiometric ages of the same samples. This, at first sight, disturbing characteristic of the annealing process turned out to be a key feature that enables the FT method to become a unique tool for deciphering the thermochronology of rocks. Temperature is the most important factor that causes annealing and, consequently, controls the degree of track shortening. Therefore, the track length distribution of a sample yields significant thermal history information over a protracted temperature range. In practice, from the single grain age and track length data a detailed thermal history can be constructed, rather than just an estimate of the timing when the sample cooled through the closure temperature.

Track densities (ρ) are in 10^5 tracks/cm², number of tracks counted (N) shown in brackets. Analyses by external detector method using 0.5 for the $4\pi/2\pi$ geometry correction factor. *Disp.*, Dispersion, according to Galbraith and Laslett (1993). Ages calculated as central ages according to Galbraith and Laslett (1993) using dosimeter glass CN5 with $\zeta_{CN5} = 345.69 \pm 8.75$ (Z. Timar-Geng). $P(\chi^2)$ is the probability of obtaining χ^2 value for ν degrees of freedom where $\nu = \text{number of crystals} - 1$

In the last decades, several annealing models for apatite have been developed to characterise FT annealing as function of time and temperature (e.g. Laslett et al. 1987; Carlson 1990; Crowley et al. 1991; Laslett and Galbraith 1996; Ketcham et al. 1999). With an inverse modelling approach, including generation of candidate t - T paths and statistical evaluation of the goodness-of-fit between model predictions and the observed data, it is possible to determine a range of thermal histories that are consistent with both the measured FT age and track length distribution (Ketcham et al. 2000). However, it has to be kept in mind that this approach does not provide an unequivocal answer in terms of a strict mathematical inversion, but offers a wide range of t - T paths that could produce the measured data. It is the task of a geologist to find the “geologically reasonable” model by constraining the range of possible thermal histories based on independent geologic evidence.

Methodological details

Twenty-eight basement samples were collected for FT analysis along an E-W oriented transect across the

southern Vosges and the southern Black Forest (Fig. 2 and Table. 1, 2). Apatite and zircon samples were separated by using conventional magnetic and heavy liquid techniques. After mounting in epoxy resin (apatite) and PFA® Teflon (zircon), grinding, and polishing, apatites were etched for 40 s in 6.5% HNO₃ at room temperature and zircons for 6–13 h in a KOH–NaOH eutectic melt at 220°C. Thermal neutron irradiation was performed at the Australian Nuclear Science and Technology Organisation (ANSTO) facility, Lucas Heights, Australia. External mica detectors were etched for 40 min in 40% HF at room temperature. Track counting and track length measurements were carried out under an optical microscope (“Axioscope” by Zeiss) with the aid of a computer driven stage (Dumitru 1993). The magnification applied was 1,600× using a dry objective for apatite FT analysis (both for track counting and confined track length measurement) and 2,500× using an oil immersion objective for zircon FT analysis. Samples were dated by the external detector method (Naeser 1976; Gleadow 1981) applying the zeta approach (Hurford and Green 1982, 1983) with a zeta value of 345.69 ± 8.75 (Durango, CN5) for apatite and 113.49 ± 1.80 (Fish Canyon Tuff, CN1) for zircon. FT ages and their graphical represen-

tations were calculated and generated by using the computer program Trackkey (Dunkl 2002). All FT ages are displayed as central ages (Galbraith and Laslett 1993) and errors are quoted as $\pm 1\sigma$.

Fission-track results

Twenty-five new zircon FT ages and twenty-eight new apatite FT ages are presented according to the I.U.G.S. recommendations (Hurford 1990) together with details of the measurement in Tables 1 and 2. Zircon and apatite FT ages, radial plots (Galbraith 1988, 1990) of single grain ages, and track length distributions are shown in Figs. 3, 4, 5, 6, 7, 8 and 9. Both zircon and apatite FT ages of the samples collected on the two flanks of the southern URG are very similar and cover the entire age range found by previous studies (Michalski 1987; Hurford and Carter 1994; Wyss 2001; Timar-Geng et al. 2004).

Black Forest

Fourteen basement samples were collected along an E–W transect with a maximum elevation difference of 1,080 m in the southern Black Forest (Fig. 2).

Zircon FT central ages range from 136 ± 16 to 312 ± 29 Ma (Fig. 3 and Table 1). No regional trend is detectable in the spatial distribution of the age data. However, a vertical trend of increasing zircon FT central ages with elevation can be observed. Radial plots of zircon samples reveal broad single-grain age distributions from ~ 500 to ~ 100 Ma (Fig. 4). In all the cases except one (ZTG013), the wide spread of single-grain ages falls into the natural Poissonian variation as obtained by the applied χ^2 statistics (Table 1); $P(\chi^2)$ values higher than 5% indicate that all grains of an individual sample belong to a single age population (Green 1981).

Apatite FT central ages range from 20 ± 2 to 83 ± 12 Ma (Fig. 3 and Table 2), the youngest ages are found in the proximity of the URG. Radial plots (Fig. 5) display a large spread of the single-grain ages between ~ 100 and ~ 5 Ma. In most of the samples, several age populations are present as revealed by the χ^2 statistics (Table 2). Track length distributions differ significantly in their shape from unimodal (e.g. ZTG013, ZTG015) to clearly bimodal (e.g. ZTG006, ZTG007, ZTG008, ZTG009, ZTG023). Confined mean track lengths range between 10.5 and 12.1 μm with relatively large standard deviations of ~ 2 to ~ 3 μm .

Fig. 3 Zircon (right side of bar) and apatite FT central ages (left side of bar) in Ma ordered according to the sections shown in Fig. 2b showing some of the weak vertical trends discussed in the text. Their respective errors are presented on Figs. 4, 5, 7 and 8

Fig. 4 Zircon FT radial plots of the Black Forest samples. An E–W topographic profile (vertical scale exaggerated by a factor of 5) with sample locations is shown at the bottom of the figure

Vosges

Along the second E–W transect in the southern Vosges, another 14 basement samples were collected with an elevation difference of 640 m (Fig. 2).

Zircon FT central ages scatter between 163 ± 16 and 254 ± 60 Ma (Fig. 3 and Table 1) without a discernible regional trend. Single-grain ages (Fig. 7) range from ~ 400 to ~ 100 Ma with no statistical indication of an extra-Poissonian variation (except ZTG102, Table 1).

Apatite FT central ages range from 26 ± 3 to 75 ± 5 Ma (Fig. 3 and Table 2) and are evenly distributed over the entire area. The vertical FT age profiles show a weak tendency to increase with an increase in elevation. Radial plots (Fig. 8) reveal a spread of the single-grain ages from ~ 100 to ~ 10 Ma. In most of the cases, $P(\chi^2)$ values are lower than 5% (Table 2), thus

indicating an extra-Poissonian variation among single-grain ages within individual samples. Bimodality in the track length distributions (Fig. 9) is less pronounced than in the Black Forest, but most of them are relatively broad. Confined mean track lengths range from 10.1 to 12.7 μm ; their standard deviations are somewhat lower than in the Black Forest ranging from 1.7 to 2.3 μm .

Thermal modelling of apatite FT data

Thermal modelling of the FT parameters was carried out with the help of the computer programme AFTSolve (Ketcham et al. 2000) by using the Laslett et al. (1987) algorithm and an initial track length of 16.3 μm . By adopting the inverse modelling approach (for details see Ketcham et al. 2000) after careful selection of fitting

Fig. 5 Apatite FT radial plots of the Black Forest samples. An E–W topographic profile (vertical scale exaggerated by a factor of 5) with sample locations is shown at the bottom of the figure

conditions, i.e. time–temperature (t – T) constraints that all cooling paths must pass through, thermal history information from apatite FT data could be derived, resulting in two differing portions of the t – T space and a best-fit path (Figs. 10, 11). The outer envelope bounds all models that provide statistically “acceptable” fits (Kolmogorov–Smirnov probability ≥ 0.05) and the inner envelope bounds all models that provide statistically “good” fits (Kolmogorov–Smirnov probability ≥ 0.5). For an exact description of the underlying statistical tests, the reader is referred to Ketcham et al. (2000). Modelling of the FT parameters was an iterative process as model runs were gradually refined by forcing limitations on the t – T paths as suggested by consecutive modelling results and geological observations. Modelling details are listed in [Appendix](#).

Black Forest

Best-fit models of the Black Forest samples indicate that there was total annealing of apatite fission tracks in the Early Cretaceous (Fig. 10). One sample next to the eastern boundary of the URG (ZTG023) cooled below track retention temperature, i.e. $\sim 120^\circ\text{C}$, not until the Palaeogene. Oldest tracks preserved in the best-fit models scatter between 43 Ma (ZTG009) and 125 Ma (ZTG009) and neither a regional trend nor a correlation with sample elevation is identifiable. Measured and predicted parameters of the best-fit paths are in very good agreement, with age goodness-of-fit values of up to 0.96 and Kolmogorov–Smirnov probabilities of up to 0.98. The modelled t – T paths of only one sample (ZTG013) failed to yield good fits to the measured data,

Fig. 6 Apatite FT length distributions of the Black Forest samples. An E–W topographic profile (vertical scale exaggerated by a factor of 5) with sample locations is shown at the bottom of the figure

but acceptable fits exhibit the same general shape as the best-fit paths of the other samples.

The modelled best-fit t – T paths exhibit very similar thermal histories for all samples. Most samples cooled below the closure temperature of the apatite FT system in the Early Cretaceous. After moderate to slow cooling below $\sim 60^\circ\text{C}$, a distinct heating event occurred in the late Eocene. This was followed firstly by slow, and then by accelerated cooling from the Miocene onwards.

Vosges

All of the samples experienced temperatures greater than 120°C in the Early Cretaceous and some of them also in the Palaeogene (Fig. 11). Best-fit models reveal oldest preserved tracks in apatite ranging between 128 Ma (ZTG124) and 37 Ma (ZTG122). Samples closer to the URG and from lower altitudes seemingly cooled later below the track retention temperature—with some

exceptions (e.g. ZTG107)—than samples further to the W and from higher altitudes. Evaluation of the statistical goodness-of-fit of modelled FT length distributions and ages to the observed data results in values between 0.69 and 0.98.

Most of the best-fit models display a two-phase cooling history, very similar to the ones obtained for the Black Forest samples. Cooling of the samples through the apatite PAZ in a time span ranging from the Early Cretaceous to the Palaeogene was followed by an Eocene heating event. The subsequent cooling phase is characterised by rapid late-stage cooling from the late Miocene onwards.

Interpretation and discussion

A question of open debate concerning the regional geology of the URG area is whether Cretaceous sediments were deposited and subsequently completely ero-

Fig. 7 Zircon FT radial plots of the Vosges samples. An E–W topographic profile (vertical scale exaggerated by a factor of 5) with sample locations is shown at the bottom of the figure

ded during the latest Cretaceous to the Paleocene (Ziegler 1990) or never existed (e.g. Geyer and Gwinner 1991). FT thermochronology can potentially contribute to the solution of this question, since it provides information on both paleotemperature and timing. The zircon FT data, particularly the existence of many grains with pre-Mesozoic ages, indicate that the sampled crustal segments never reached the critical temperature for complete track loss, i.e. $\sim 330^\circ\text{C}$ (Tagami and Shimada 1996; Tagami et al. 1998), after post-Variscan peneplanation. Zircon FT central ages as well as single-grain ages scatter significantly. χ^2 statistics (Table 1) indicate that the observed large spread in single-grain ages generally does not represent a real difference to the respective apparent age because $P(\chi^2)$ values are (with exception of the sample ZTG102) consistently higher than 5% (Green 1981). However, due to the low number of random samples (20 counted grains or fewer) and the high standard errors of single-grain age estimates the χ^2

approach may lack power to detect any extra-Poissonian variation (Timar-Geng et al. 2004). Thus, the observed high spread may reflect different track retentivity of the individual grains within one sample, for instance due to variable amounts of accumulated α damage (Kasuya and Naeser 1988). Based on this assumption, the zircons with the youngest single-grain ages can be interpreted as having the lowest thermal stability because they are the last to close on a cooling path (Brandon et al. 1998). The youngest single-grain age represents the maximum age dating the passage of the sample through the cool limit of the zircon FT PAZ (Fügenschuh and Schmid 2003). Continuous hydrothermal activity in the Jurassic (e.g. Wernicke and Lippolt 1997; Wetzel et al. 2003) caused substantial annealing of fission tracks in zircon (Timar-Geng et al. 2004) and a long residence time within the PAZ. This is also suggested by the broad distribution of zircon single-grain ages in the present dataset. Based on these observations it can be inferred that the sampled

Fig. 8 Apatite FT radial plots of the Vosges samples. An E–W topographic profile (vertical scale exaggerated by a factor of 5) with sample locations is shown at the bottom of the figure

level of the crust cooled below $\sim 230^{\circ}\text{C}$ (the cool limit of the zircon PAZ after Tagami et al. 1998) during the Early Cretaceous. Since the Permo-Triassic paleosurface is partly preserved in the southern Black Forest (e.g. Paul 1955; Wimmenauer and Schreiner 1990), it can be assumed that no significant erosion of the pre-Mesozoic basement has been occurred. Taking a generous estimate of $\sim 1,500$ m Mesozoic sediment cover, based on interpolated isopach maps (e.g. Geyer and Gwinner 1991), it is obvious that the observed paleotemperatures in the Early Cretaceous cannot be due to burial alone (see also Timar-Geng et al. 2004), even not if a hypothetical kilometre-scale thick Upper Jurassic to Lower Cretaceous pile of sediments is assumed (Fig. 12).

The t – T path between $\sim 230^{\circ}\text{C}$, given by the youngest cluster of zircon FT single-grain ages, and $\sim 120^{\circ}\text{C}$, marking the entrance of the samples into the apatite PAZ, is only poorly constrained. However, it appears that the Cretaceous must have been a period of acce-

lerated cooling, since some of the modelled t – T paths enter the apatite PAZ already at the end of the Early Cretaceous. This could have been caused primarily by the cessation of the hydrothermal activity in the area in combination with the uplift-induced erosion of the so-called “Rhenish Shield” (Cloos 1939).

From the Early Cretaceous onwards, the thermal history of the flanks of the southern URG is tightly constrained by the apatite FT modelling results. Best-fit models display a fairly common t – T path for all samples with a two-phase cooling history. It starts with entering the apatite PAZ in Early Cretaceous to Palaeogene times depending on the position of the samples. Overall cooling is interrupted by a distinct heating event in the late Eocene that is invariably recorded by all samples. Subsequent cooling to surface temperatures is characterised by an accelerated rate from the Miocene onwards. This can reflect amplified erosion due to uplift of the Vosges–Black Forest area owing to lithospheric

Fig. 9 Apatite FT length distributions of the Vosges samples. An E–W topographic profile (vertical scale exaggerated by a factor of 5) with sample locations is shown at the bottom of the figure

folding (Dèzes et al. 2004). However, this late cooling episode can also be an artefact of the Laslett et al. (1987) annealing model (e.g. Ketcham et al. 2000) and should be considered with caution. In contrast, the other parts of the t – T paths, especially the timing of entry into the PAZ and the temperature maximum and timing of a transient heating episode, are well reconstructed by thermal modelling studies (Gleadow and Brown 2000). A complex cooling history is also evidenced by the frequent bimodal distributions of apatite FT lengths (e.g. the Todtnauberg profile in the Black Forest; Fig. 6). One generation of tracks is severely annealed (with track lengths of 8–10 μm) due to the Eocene thermal episode and a second generation formed after the temperature peak has longer tracks in the range of 12–14 μm.

To gain information on the denudation history of the flanks of the URG, two transects with an elevation difference of 640–1,080 m were sampled. Such a vertical reference frame can be used to estimate the rate of denudation (Gallagher et al. 1998). Samples collected

over considerable relief often yield apatite FT ages that display a positive correlation with sample elevation (e.g. Wagner et al. 1977). For high denudation rates, such as in active orogenic belts, the gradients of the age–elevation profiles correspond closely to the denudation rates (Gleadow and Brown 2000). For low denudation rates, these linear profiles are replaced by concave-upwards curves and are interpreted as representing prolonged residence in the PAZ. In this case, the age–elevation profiles are not related to denudation rate. An important pre-requisite in order to obtain information on denudation from such profiles is that the samples were taken within a single tectonic unit. Another essential requirement is that the samples cover a significant range of vertical relief that may render possible to contain a complete frozen paleo-PAZ. Unfortunately, none of these preconditions are fulfilled in this study and the apatite FT age–elevation profiles (Fig. 13) show substantial disturbance. Even though, a tendency towards increasing ages with increasing elevation is recognizable

Fig. 10 Modelled best-fit t - T paths and two envelopes covering the statistically “acceptable” fits (light grey) and “good” fits (dark grey) from the Black Forest. K-S test: Kolmogorov–Smirnov test evaluating the degree of fit between FT length distributions. Age

GOF: FT age goodness-of-fit test. For methodological details, see Ketcham et al. (2000). An E–W topographic profile (vertical scale exaggerated by a factor of 5) with sample locations is shown at the bottom of the figure

(Fig. 13). However, in the present case the distribution of FT age with elevation points to progressive annealing as a result of increasing temperature and it is not associated to any cooling rate. For a sound interpretation of the data in terms of a quantitative assessment of amount and rate of denudation, both FT age and length measurements have to be incorporated. Temperature and timing of the thermal maximum prior to the final cooling to surface temperatures are quite well determined from modelling studies (Gleadow and Brown 2000). These paleotemperature estimates can be used to derive constraints on the amount of denudation (e.g. Raab et al. 2002). Temperature can be equated to burial depth using the following equation:

$$D = (T - T_s)/G$$

where D is the thickness of the denuded section (km), T , the modelled paleotemperature (°C), T_s , the surface temperature (°C) and G , the geothermal gradient (°C/km). Despite the considerable variation among the observed apatite FT ages, the modelled thermal histories suggest a common timing for the onset of the last cooling phase in the late Eocene. These t - T points

can be used to estimate the amount of denudation since the late Eocene (Table 3). Modelling of the apatite FT parameters suggest a distinct heating episode in the late Eocene contemporaneous to the initial rifting phase of the URG (e.g. Schumacher 2002) and associated volcanic activity (Keller et al. 2002). This clearly points to a possible elevated paleogeothermal gradient during this time. The denudation estimates for gradients of 45 and 60°C/km are given in Table 3. For the latter case, they range between 1.0 and 1.7 km correlating quite well with the present elevation of the samples (Fig. 14). Conversely, taking into account up to 1,500 m, Mesozoic sedimentary rocks based on geological observations and the fact that only minor amounts of crystalline basement are being eroded, the observed annealing requires elevated paleotemperatures in the late Eocene.

Minor differences in the amount of denudation can be explained by Tertiary differential block movements. For example, in the eastern Vosges, N–NE trending Paleozoic discontinuities were reactivated as normal faults during the E–W extension in the Oligocene (Edel and Fluck, 1989).

Fig. 11 Modelled best-fit t - T paths and two envelopes covering the statistically “acceptable” fits (light grey) and “good” fits (dark grey) from the Vosges. K-S test: Kolmogorov–Smirnov test evaluating the degree of fit between FT length distributions. Age

GOF: FT age goodness-of-fit test. For methodological details, see Ketcham et al. (2000). An E–W topographic profile (vertical scale exaggerated by a factor of 5) with sample locations is shown at the bottom of the figure

It may be worthwhile noting explicitly that it is inappropriate to interpret the measured apatite FT ages in the URG as cooling ages, particularly, because one of

several requirements, a steady-state paleogeothermal gradient, is definitively not met throughout the low-temperature thermal history of the southern URG. The FT age–elevation profiles do not result from simple linear cooling in the upper crust.

Fig. 12 Relationship between the paleogeothermal gradient (p) and the hypothetical burial (b) of the present earth's surface for the Early Cretaceous. Paleotemperature: $\sim 230^\circ\text{C}$ (the cool limit of the zircon PAZ after Tagami et al. 1998); assumed surface temperature: 10°C . The FT results cannot be explained by burial depth, since such high values up to 7 km are impossible to reconcile with the known geology of the URG area

Conclusions

The FT data demonstrate that the flanks of the southern URG have experienced a complex thermal history with repeatedly changing paleogeothermal gradients. Using an inverse modelling approach, the low-temperature thermal history of the area could be determined that is consistent with the measured FT dataset and independent geological observations.

Interpreting the youngest cluster of zircon FT single-grain ages as the approximate date of cooling through the cool limit of the zircon FT PAZ, and interpolating the thickness of the Mesozoic sedimentary rocks from adjacent regions into the study area, it can be inferred that not even a hypothetical kilometre-thick cover of Upper Jurassic to Lower Cretaceous sediments could have caused the observed very high paleotemperatures.

Fig. 13 Apatite FT age versus elevation profiles from the Black Forest and Vosges

The reason for the observed thermal anomaly is ascribed to one or (very probably) repeated Mesozoic hydrothermal episodes (see also Timar-Geng et al. 2004). Thus, the question regarding the thickness of the Cretaceous sediments in the southern URG area cannot be answered on the basis of FT analysis alone.

Modelling results provided a comprehensive thermal history of the study area from the Early Cretaceous to present. It is characterised by complex cooling with a transient heating episode in the late Eocene. This heating phase is contemporaneous to the initial rifting stage of the URG and associated with increased volcanic activity.

Based on best-fit t - T paths and a tentative estimation of the prevailing paleogeothermal gradient in the late Eocene, the total amount of the denuded section from the flanks of the URG could be estimated. It amounts to

1.0–1.7 km for a paleogeothermal gradient of 60°C/km and 1.3–2.2 km for a paleogeothermal gradient of 45°C/km, respectively.

Apatite FT central ages from the URG area not only record cooling due to tectonic uplift alone, but also due to decreasing hydrothermal activity. Therefore, no uplift rates based on age–elevation profiles can be derived. Convective heat transport seems to have played an important role throughout the post-Variscan thermotectonic evolution of the region. Therefore, only the thermal modelling approach can offer a meaningful interpretation of the growing amount of FT data.

Appendix**Modelling details**

This appendix (Table 4, 5) contains information about parameters used for inverse modelling. The time for the first constraint was chosen based on the consideration that this time should be somewhat earlier than the FT age of the oldest and thus most resistant apatite grains to allow for age reduction by partial annealing (Ketcham et al. 2000). Thus, the temperature for the first constraint was set at $\sim 130^\circ\text{C}$ providing that there are no fission tracks present as an initial condition. Modelled t - T paths were initially defined to be non-monotonic, aiming at finding solutions by the program, particularly any possible heating events and their timing. The initial model runs also constrain the time of cooling below the track retention temperature, which can be used as initial constraints for subsequent model runs. In a next step, the new initial constraint and additional intermediate constraints were used to better evaluate individual heating and cooling events. Model runs were so gradually refined by forcing restrictions on the t - T paths as suggested by consecutive modelling results and geological observations.

Key words: Northern Switzerland, low-temperature thermochronology, fission track analysis, Nagra boreholes

ABSTRACT

New zircon and apatite fission track (FT) data from four boreholes, which penetrate the Mesozoic and pre-Mesozoic sediments and crystalline basement of northern Switzerland, are presented. Inverse thermal modelling of the measured apatite FT parameters unravels the low-temperature (below ~120 °C) thermal history of the crystalline basement of northern Switzerland. Zircon FT central and single-grain ages cluster around 250 Ma, thus maximum palaeotemperatures did not exceed ~330 °C after late-Variscan consolidation of the crystalline basement. Apatite FT central ages vary between 25 and 87 Ma. Confined mean track lengths range between 9.3 µm and 11.6 µm, suggesting substantial track annealing within all apatite samples. Modelled time-temperature paths offer a clear picture about the low-temperature thermal history of the crystalline basement of northern Switzerland: Cretaceous cooling is followed by an Eocene heating event and subsequent cooling to present-day temperatures. The Eocene heating episode is contemporaneous with the initial rifting stage of the nearby Upper Rhine Graben and the associated increasing volcanic activity. Crustal-scale faults of the Permo-Carboniferous Trough of northern Switzerland could have acted as major pathways for circulating hydrothermal fluids giving rise to the observed Middle to Late Eocene thermal event.

ZUSAMMENFASSUNG

Neue Zirkon- und Apatit-Spaltspurdaten werden aus vier Bohrungen, welche die mesozoische und pre-mesozoische Sedimentbedeckung, sowie das oberste kristalline Grundgebirge der Nordschweiz durchteufen, vorgelegt. Inverse thermische Modellierung der gemessenen Apatit-Spaltspurparameter erlaubt, die Niedrigtemperaturgeschichte (unter ~120 °C) des kristallinen Grundgebirges der Nordschweiz zu enträtseln. Die Zirkon-Spaltspuralter (Zentralalter) und die Einzelkornalter zeigen eine Häufung um 250 Ma. Daraus folgt, dass die maximalen Paläotemperaturen nach der spätvariszischen Konsolidierung des Kristallins ~330 °C nicht mehr überschritten haben. Apatit-Spaltspuralter (Zentralalter) variieren zwischen 25 und 87 Ma. Die mittleren Spaltspurlängen reichen von 9,3 µm bis 11,6 µm und weisen auf eine substantielle Ausheilung in den Apatiten hin. Die modellierten Zeit-Temperatur-Pfade bieten ein klares Bild der Niedrigtemperaturgeschichte des kristallinen Grundgebirges in der Nordschweiz: Einer kretazischen Abkühlung folgt ein eozänes Wärmeeignis und anschliessend eine Abkühlung zur heutigen Temperaturverteilung. Der eozäne Wärmepuls ist zeitgleich mit der initialen Riftingphase des nahegelegenen Oberrheingrabens und der damit verbundenen erhöhten vulkanischen Aktivität. Zum Nordschweizer Permo-karbondrog-System gehörige Störungen im Krustenmassstab könnten als Fließwege für zirkulierende Fluide gedient haben, die zum beobachteten mittel- bis späteeozänen thermischen Ereignis führten.

1. Introduction

The trend and the shape of fission track (FT) age-depth (or age-elevation) profiles provide important constraints on the thermal history of crustal segments. Most commonly ages decrease with depth. In a typical foreland basin, however, detrital FT ages might record the erosion history of the hinterland (e.g., Cederbom et al. 2004), and in some rare cases FT ages represent formation ages of, for example, volcanic ashes and, hence, are consistent with the chronostratigraphy (e.g., Naeser et al. 1987). The age-depth graphs vary from nearly linear in active orogenic belts to concave-upwards in cratonic regions

with extremely low cooling rates, or alternatively, in sedimentary basins with slow heating due to progressive burial (e.g., Gleadow & Brown 2000). Significant acceleration of the cooling rate after a period of relative stability leads to a compound profile with a typical “break in slope”, interpreted as the onset of rapid cooling (e.g., Gleadow & Brown 2000). Moreover, vertical sections are very convenient, when time-temperature paths experienced by individual samples are modelled, because the palaeogeothermal gradient at different times can be indirectly determined. Thus, the information from a vertical

Fig. 1. (a) Tectonic sketch map and (b) schematic profile of the study area (after Thury et al. 1994).

alignment of samples is markedly better than that from any individual sample alone, provided that the samples did not experience tectonic displacements relative to each other during or after their recorded thermal histories. In regions with relatively low relief vertically aligned samples from deep boreholes are particularly favourable, since approximations to a true vertical section are possible only in mountainous regions with high relief. This sampling approach has led to many successful applications of FT analysis on borehole cores evaluating the thermal history of sedimentary basins (e.g., Gleadow et al. 1983; Green et al. 1989; Duddy 1994; Tingate & Duddy 2002; House et al. 2002) or revealing the palaeothermal anomalies in different geological settings (Green et al. 2001; Murakami et al. 2002).

Due to the lack of substantial relief in northern Switzerland, the analysis of borehole samples, in addition to surface

samples, is essential for a sound determination of the thermal history of the region.

In the course of an extensive geological investigation program for the assessment of the feasibility and safety of a repository for radioactive waste, Nagra (Swiss National Cooperative for the Disposal of Radioactive Waste) carried out several drillings in central northern Switzerland. Results are summarised in a number of reviews (e.g., Thury et al. 1994; Müller et al. 2002; Nagra 2002). In addition, the burial and the associated thermal history of the Molasse basin have been investigated by, for instance, Schegg & Leu (1998), and Nagra (2002). Applying a 1D basin modelling approach, Nagra (2002) postulated two heating events for the crystalline basement and the Mesozoic cover, a first one during the Early Cretaceous and a second one in the Late Miocene. These heating events are supported by available apatite FT modelling results (Mazurek et al. 2006).

This paper presents new zircon and apatite FT data from four of the Nagra boreholes (Fig. 1) and uses these data as input parameters for modelling the time-temperature paths experienced by the samples. The focus lies on the pre-Mesozoic crystalline basement and the Permo-Carboniferous Trough of northern Switzerland. The differences between the new results and the previous FT modelling results related to the thermal history of the Molasse basin (Mazurek et al. 2006) are also discussed. Finally, also the relationship to the FT results from the adjacent Upper Rhine Graben area (Timar-Geng et al. 2004; 2006) is investigated. This article provides new insights into the low-temperature thermal history of northern Switzerland and makes an important contribution to the assessment of safe disposal of radioactive waste in northern Switzerland.

2. Geological setting

Five main tectonic units are distinguished in northern Switzerland and adjacent SW Germany (Fig. 1): a) the crystalline basement, exposed in the Black Forest; b) the Permo-Carboniferous Trough of northern Switzerland which is not exposed at the surface; c) the autochthonous sedimentary cover of the Tabular Jura and the Swabian Alb; d) the sheared-off sedimentary cover comprising the Folded Jura and the Molasse Basin, and e) the Tertiary rift sediments of the Upper Rhine Graben.

The Late Palaeozoic consolidation of the crystalline basement of northern Switzerland was preceded by extensive Variscan deformation and metamorphism, accompanied by substantial magmatic activity, and the formation of the Permo-Carboniferous Trough of northern Switzerland (for details see overviews by, e.g., Thury et al. 1994; Müller et al. 2002). Well-stratified Triassic to Jurassic deposits accumulated in a shallow epicontinental sea and indicate relative tectonic stability. However, episodic reactivation of pre-existing basement structures during the Jurassic led to differential subsidence and synsedimentary deformation, documented by changes of facies and sediment thickness (Wetzel et al. 2003). Reactivated faults also acted as major conduits for hot fluids in the crystalline basement, as documented by Jurassic hydrothermal mineralisations, exposed, for example, in the nearby Black Forest and Vosges (for a compilation, see Wetzel et al. 2003). Mesozoic heating is also evidenced by palaeomagnetic data from the Vosges (Edel 1997), documenting post-Permian thermal overprinting. FT data from the southern Upper Rhine Graben area indicate that the Jurassic hydrothermal fluid migration affected the upper crust on a regional scale (Timar-Geng et al. 2004, 2006). Thus, it is very likely that substantial heating also occurred in the crystalline basement of northern Switzerland. A significant stratigraphic gap between the Upper Jurassic and middle Eocene deposits provides evidence of Cretaceous to early Tertiary erosion. However, it is still a matter of debate, how much Cretaceous sediments were deposited and subsequently eroded (e.g. Ziegler 1990).

Fig. 2. Stratigraphic overview of the Nagra boreholes with zircon (in white letter on black background) and apatite FT central ages (black letter on white background). All ages are given with their 1 σ error. The boreholes are leveled according to their common Mesozoic base unconformity. Waved horizontal lines indicate unconformities.

The Tertiary geological history of northern Switzerland and adjacent areas is a period of renewed tectonic activity, mainly related to Alpine orogeny. It includes the Eo-Oligocene subsidence of the Upper Rhine Graben, the subsequent updoming of the southern Black Forest, the subsidence of the Alpine foreland from the Late Oligocene onwards, and finally, the Late Miocene formation of the Jura Mountains. Ongoing tectonic activity is clearly documented for northern Switzerland and the southern Upper Rhine Graben area by the well-known increased seismicity (several strong earthquakes in historical times; see compilation by Müller et al.

2002) and by the deformation of Pliocene fluvial gravels (Giamboni et al. 2004a) and Quaternary terraces (Giamboni et al. 2004b).

3. Methodology

3.1 Basics of FT analysis

FT analysis of zircon and apatite is a powerful tool in assessing the thermal history of rocks in the temperature range of ~ 60–300 °C, which characterises the upper few kilometres of the crust. It is based on the spontaneous nuclear fission of ^{238}U (Price & Walker 1962a, 1962b) inducing a damage trail in the crystal, i.e. the latent fission tracks. After revelation of the latent tracks by chemical etching of polished grain-internal surfaces, the spontaneous track density may be counted. The FT age is calculated from the ratio of the spontaneous track density N_s observed on the polished surface and the induced track density N_i measured in an external detector after an irradiation procedure. A detailed overview of the principles of FT dating was provided, for instance, by Wagner & Van den Haute (1992), Gallagher et al. (1998) and Gleadow & Brown (2000).

The linear damage trails are stable over geological time only at relatively low temperatures and they become shorter by a process known as annealing at elevated temperatures. This reduction in length depends on the maximum temperature that each individual FT has experienced after its formation. Apart from other factors (e.g. chemistry, α -damage) temperature and time are clearly the most important factors for annealing of fission tracks. Since new tracks are continuously produced due to spontaneous decay, characteristic track length distributions can result depending on the thermal history to

which the mineral grain has been exposed. Thus, the process of annealing is the key to the study of thermal histories by FT analysis. Modelling of FT annealing allows constraining the thermal history of rocks by matching observed and modelled FT parameters (FT age and length distribution).

3.2 Analytical details

Seventeen samples from drill cores of four Nagra boreholes were collected (Fig. 2, Table 1). After crushing and sieving, mineral separation was performed using conventional magnetic and heavy liquid techniques. Apatites were mounted in epoxy resin, zircons in PFA® Teflon. A sequence of grinding and polishing steps was carried out on the mounts in order to reveal grain-internal surfaces. Apatites were etched for 40 sec in HNO_3 (6.5 %) at room temperature, zircons for 4 to 14 h in a KOH-NaOH eutectic melt at 220 °C. Thermal neutron irradiation was carried out at the Australian Nuclear Science and Technology Organisation (ANSTO) facility, Lucas Heights, Australia. External mica detectors were etched for 40 min in HF (40 %) at room temperature. Tracks were counted and measured under an optical microscope with the aid of a computer driven stage (Dumitru 1993). Magnification used was 1600× using a dry objective for apatite FT analysis (track counting and confined track length measuring) and 2500× using an oil immersion objective for zircon FT analysis. FT ages were calculated according to the external detector method (Naeser 1976; Gleadow 1981) and the zeta approach (Hurford & Green 1982, 1983) with a zeta value of 345.69 ± 8.75 (Durango, CN5) for apatite and 113.49 ± 1.80 (Fish Canyon Tuff, CN1) for zircon. FT age and error calculation as well as the generation of the graphical representation were

Fig. 3. Apatite FT central age (with 1σ error) versus depth graphs of the investigated Nagra boreholes. The Leuggern samples are splitted in two separate age groups as indicated by their thermal modelling results.

Fig. 4. Mean track length versus depth graphs of the investigated Nagra boreholes.

performed by the computer program Trackkey (Dunkl 2002). All FT ages are central ages (Galbraith & Laslett 1993) and errors are quoted as $\pm 1\sigma$.

Thermal modelling of the apatite FT data was performed using the computer program AFTSolve (Ketcham et al. 2000) and the algorithm of Laslett et al. (1987), which is a numerical characterization of apatite FT annealing as a function of time and temperature. It is assumed that there is no significant difference in the annealing behaviour between the apatites of this study and the Durango apatite on which the algorithm of Laslett et al. (1987) is based. In this study an inverse modelling approach was carried out: a set of t-T paths was assessed that is consistent with the measured FT data in apatite and other geological constraints. The modelling process includes the generation of a large number of potential t-T paths and the statistical evaluation of the quality of the fit between predicted (based on

each t-T path generated) and the measured FT data in apatite (for details see Ketcham et al. 2000). As a result two regions outline all “acceptable” fits (light grey regions) with a Kolmogorov-Smirnov probability of 0.05 or more and “good” fits (dark grey regions) with a Kolmogorov-Smirnov probability of 0.5 or more (Ketcham et al., 2000). The best-fit t-T path is also included in each diagram. However, it has to be noted that the envelopes do not encompass t-T fields in which *all* t-T paths pass the corresponding statistical tests.

4. Analytical results

Seventeen core samples yielded fourteen zircon and sixteen apatite ages. Both zircon and apatite FT central ages are very similar in all boreholes, zircon FT central ages in total varying between 185 ± 16 Ma and 287 ± 21 Ma (Fig. 2, Table 2) and ap-

Ages calculated as central ages according to Galbraith and Laslett (1993) using dosimeter glass CN1 with $\xi_{CN1} = 113.49 \pm 1.80$ (Z. Timar-Geng).

$P(\chi^2)$ is the probability of obtaining χ^2 value for ν degrees of freedom where ν = number of crystals - 1.

apatite FT central ages varying between 25 ± 2 Ma and 87 ± 6 Ma (Fig. 2, Table 3) with a trend of decreasing ages with depth (Fig. 3). Mean track lengths exhibit a similar decreasing tendency with increasing borehole depth (Fig. 4).

4.1 Kaisten

In the Kaisten borehole metapsammitic layers of the crystalline basement beneath 172 m sediments of the Permian trough shoulder were sampled from a depth range between 407 m and 1306 m and present-day temperatures of 28° to 58° °C (Table 1).

Two samples yielded similar zircon FT ages of 233 ± 21 Ma and 245 ± 22 Ma from the top and the bottom of the entire sampled depth range (Figs. 2, 5). Radial plots (Galbraith 1988, 1990) of both zircon samples display relatively broad single-grain age distributions from ~ 400 to ~ 130 Ma. This high scatter of single-grain ages can be explained with normal Poissonian variation as revealed by the applied χ^2 statistics (Table 2), i.e. $P(\chi^2)$ values $>5\%$ indicate that all grains analysed for individual samples may be derived from a single age population (Green 1981). However, Timar-Geng et al. (2004) showed that high standard errors of single-grain age estimates and the low number of counted grains can render the χ^2 -approach unsuitable for detection of any extra-Poissonian variation due to, for instance, different annealing kinetics of the individual grains.

Apatite FT ages vary from 45 ± 3 Ma at the bottom to 87 ± 6 Ma at the top of the sampled depth range with a clear younging trend toward depth (Figs. 2, 5). Single-grain ages scatter between ~ 140 Ma and ~ 30 Ma, the two youngest samples (Kai1 and Kai2) revealing very low $P(\chi^2)$ values (Table 3), which is an indication of extra-Poissonian variation in the spread of these ages. Confined mean track lengths ranging between $10.6 \mu\text{m}$ and $11.6 \mu\text{m}$ together with standard deviations all greater than $1.4 \mu\text{m}$ (Fig. 5) clearly show substantial partial annealing of all samples. In addition, decreasing apatite FT ages correlate with decreasing track lengths.

4.2 Riniken

Riniken is the only borehole of this study that penetrates the deep Permo-Carboniferous trough of northern Switzerland (Nagra 1990). Permian breccias and sandstones were sampled from a depth range between 992 m and 1797 m (Table 1).

Zircon FT central ages scatter between 238 ± 14 Ma and 287 ± 21 Ma (Figs. 2, 6). The large spread in single-grain ages (~ 460 Ma to ~ 130 Ma) with a significant proportion of pre-depositional single-grain ages indicate that none of the samples experienced palaeotemperatures critical for complete annealing of fission tracks in zircon, i.e. $\sim 330^\circ$ °C (Tagami & Shimada 1996; Tagami et al. 1998) since deposition. Thus, these samples exhibit a strong inherited signal from the source region.

Table 3. Apatite FT age data from four boreholes (Nagra) in Northern Switzerland

Track densities (ρ) are in 10^5 tracks/cm², number of tracks counted (N) shown in brackets.

Analyses by external detector method using 0.5 for the $4\pi/2\pi$ geometry correction factor.

Ages calculated as central ages according to Galbraith and Laslett (1993) using dosimeter glass CN5 with $\xi_{CN5} = 345.69 \pm 8.75$ (Z. Timar-Geng).

$P(\chi^2)$ is the probability of obtaining χ^2 value for ν degrees of freedom where ν = number of crystals - 1.

Apatite FT central ages range between 58 ± 3 Ma and 72 ± 5 Ma (Figs. 2, 6) with only a weak tendency of decreasing ages with depth. Radial plots (Fig. 6) display a large spread in the single-grain ages, varying between ~ 160 Ma and ~ 25 Ma. In all of the samples multiple age populations are present as revealed by the χ^2 statistics (Table 3). Substantial annealing is indicated by short confined mean track lengths of $9.3 \mu\text{m}$ to $10.2 \mu\text{m}$ and standard deviations greater than $1.7 \mu\text{m}$.

4.3 Leuggern

A two-mica granite at the bottom and paragneisses at shallower depths were sampled in the Leuggern borehole between 567 m and 1684 m depth (Table 1).

Three samples yield uniform zircon FT central ages of 245 ± 19 Ma at the bottom, 244 ± 25 Ma at the top and 264 ± 25 Ma in-between (Figs. 2, 7). Single-grain ages range between ~ 450 Ma and ~ 140 Ma with no statistical indication for extra-Poissonian variation (Table 2).

Apatite FT central ages vary between 25 ± 2 Ma and 68 ± 4 Ma with a striking jump in the FT ages between Leu2 and Leu3 (Fig. 7). This feature is also visible in the confined mean track lengths, the two younger samples (Leu1 and Leu2) having longer mean track lengths ($11.3 \mu\text{m}$ and $11.2 \mu\text{m}$) than the older ones (Leu3 and Leu4 with mean track lengths of $10.1 \mu\text{m}$), but *not* in the zircon FT central ages. Standard devia-

tions are greater than $1.8 \mu\text{m}$. A distinction in two age groups is also reflected in the single-grain age distributions. Radial plots of the two younger samples (Leu1 and Leu2) display a single-grain age variation between ~ 60 Ma and ~ 10 Ma, while the older ones (Leu3 and Leu4) reveal a distribution of significantly older single-grain-ages from ~ 120 Ma to ~ 40 Ma (Fig. 7). Only Leu1 reveals a statistically founded indication for multiple age populations (Table 3).

4.4 Siblingen

Cordierite-biotite- and cordierite-two-mica-granites were sampled in the Siblingen borehole between 639 m and 1519 m depth (Table 1).

Zircon FT central ages scatter between 185 ± 16 Ma and 240 ± 23 Ma (Figs. 2, 8). There is a large spread in single-grain ages (~ 470 Ma to ~ 100 Ma), but only the sample at the bottom of the borehole (Sib1) has a $P(\chi^2)$ value lower than 5% (Table 2), thus indicating extra-Poissonian variation. Such isolated variation could be due to different annealing kinetics of the individual grains.

Apatite FT central ages range between 47 ± 3 Ma and 80 ± 7 Ma (Figs. 2, 8) with a clear tendency of decreasing ages with depth. Contrary to the zircon FT results Sib1 is the only sample showing no extra-Poissonian variation with a relatively narrow range of single-grain ages (~ 80 Ma to ~ 30 Ma). Radial

Fig. 5. Kaisten borehole: radial plots and track length distributions. For data, see Tab. 2 (zircon) and Tab. 3 (apatite). For geological unit patterns, see Fig. 2.

plots of the other samples reveal single-grain ages up to ~ 130 Ma (Fig. 8). Confined mean track length in Sib3 (the only sample with the standard amount of 100 measurable confined horizontal tracks) is $10.8 \pm 1.9 \mu\text{m}$.

5. Thermal modelling

5.1 Modelling strategy

The low-temperature thermal history of northern Switzerland was derived using the following modelling strategy: Initial model runs were performed with only a few constraints on the time-temperature (t-T) path of each sample. The time for the first constraint was chosen on the base of the zircon FT age of the same sample and the oldest apatite single-grain age. This date should be somewhat older than the FT age of the oldest and thus most resistant apatite grains to allow for age reduction by partial annealing (Ketcham et al. 2000). The temperature for the first constraint was set at $\sim 130^\circ\text{C}$ ensuring that there are no apatite fission tracks present as an initial condition. The last time constraint was set at the temperature at which the sample was collected (Nagra 1990, 1991a, 1991b, 1993). Modelled t-T paths were defined to be non-monotonic. This configuration is aimed at finding solutions by the program, particularly any possible heating events and their timing. This first model runs also constrain the time of cooling of the

Fig. 6. Riniken borehole: radial plots and track length distributions. For data, see Tab. 2 (zircon) and Tab. 3 (apatite). For geological unit patterns, see Fig. 2.

sample below the track retention temperature, which can be used as a new constraint for following model runs.

In a next step, the new initial constraint and additional intermediate constraints (Table 4) were used to better evaluate individual heating and cooling events. Thereby model runs were progressively refined by forcing restrictions on the t-T paths as suggested by successive modelling results using additional nodal points in the region of assumed thermal events. Several possibilities regarding the timing of such a heating event were tested in an effort to find the temperature peak most consistent with the measured data. In a final step a narrower search was carried out using monotonic t-T paths between two user-defined constraints. This option potentially reduces the full extent of the envelope of statistically acceptable solutions, but simultaneously disables the modelled t-T paths to bounce up and down in a geologically inappropriate fashion (Ketcham et al. 2000). An example of the modelling procedure up to the “final” result is illustrated for sample Kai2 (Fig. 9).

5.2 Model results

5.2.1 Kaisten

Modelling of the apatite FT data from the Kaisten borehole samples (Fig. 10) indicates total track annealing since the be-

Fig. 9. Illustration of the modelling procedure (sample Kai2). From left to right: initial step with only a few constraints and non-monotonic t-T paths; intermediate step with more restrictions, as suggested by first model runs (e.g. initial constraint at 90 Ma) but still with non-monotonic t-T paths; “final” result with monotonic t-T paths between user-defined constraints.

ginning of the Mesozoic subsidence. Thus, the maximum palaeo-temperatures after post-Variscan peneplanation exceeded 120 °C. Oldest tracks preserved in the best-fit models vary from 75 Ma at the bottom of the sampled depth interval to 115 Ma at the top. This trend of increased track annealing with depth is consistent with the age data and can be interpreted in terms of increasing down-hole palaeo-temperatures. Measured and predicted parameters of the best-fit paths are in very good agreement, with age goodness-of-fit values of up to 0.98.

All four models (Fig. 10) display a two-phase cooling history since the samples cooled below the track retention temperature of ~120 °C. Moderate to rapid Cretaceous cooling through the apatite partial annealing zone (PAZ), i.e. through 120 °C to 60 °C, was followed by an Eo-Oligocene heating event and subsequent slow cooling to present-day temperatures. During the late cooling phase all samples remained within the PAZ until comparatively recent times.

5.2.2 Riniken

Best-fit models of the Riniken samples (Fig. 11) suggest that there was total annealing of fission tracks in Mesozoic times. Oldest tracks preserved in the best-fit models scatter between 113 Ma and 154 Ma. Evaluation of the statistical goodness-of-fit of modelled FT length distributions and ages to the measured data yields values between 0.63 and 0.99 (Fig. 11).

The modelled best-fit t-T paths are very similar for all samples. After Late Jurassic to Cretaceous cooling below the closure temperature of the apatite FT system a new heating phase started in the Late Eocene. After this heating event annealing temperatures persisted until recent times, which is also implied from the scarcity of very long tracks (Fig. 6).

5.2.3 Leuggern

The modelled t-T paths of the Leuggern borehole samples show two groups of markedly different shape (Fig. 12). The two upper samples (Leu3 and Leu4) experienced last resetting

of the apatite FT system in Mesozoic times. Best-fit models of the two lower samples (Leu1 and Leu2) indicate total annealing during the Eocene preserving oldest tracks with an age of 37 Ma (Leu1) and 48 Ma (Leu2). Preserved oldest tracks in the best-fit models of the two other samples are significantly older (118 Ma and 121 Ma). The statistical precision of the best-fit t-T paths is especially good for the two samples with short thermal histories (Leu1 and Leu2) with goodness-of-fit values >0.95. Somewhat lower but still “good” values were obtained for the two upper samples (Fig. 12).

Modelled t-T paths of both Leu3 and Leu4 display a common thermal history. Initial cooling below track retention temperatures in Cretaceous times and subsequent residence at moderate temperatures were followed by a prominent heating event during the Eocene. After this heating episode the samples remained within the PAZ until almost recent times. Apatite FT data of the two other samples (Leu1 and Leu2) recorded only the last cooling phase since the Eocene (Fig. 12).

5.2.4 Siblingen

Best-fit models of the Siblingen borehole samples (Fig. 13) indicate total annealing of apatite fission tracks during the Cretaceous. Oldest tracks preserved in the best-fit models range from 74 Ma (bottom) to 115 Ma (top), displaying a trend of increased track annealing with depth. Excellent age goodness-of-fit values of up to 0.99 prove that measured FT data and predicted parameters of the best-fit paths are in very good agreement.

All three models (Fig. 13) exhibit very comparable thermal histories with two cooling phases separated by a distinct heating event. The first cooling phase started in Cretaceous times and is characterised by moderate to rapid cooling rates. This cooling phase is followed by a heating event during the Eocene and a subsequent slow cooling phase to present-day temperatures. During the last cooling phase annealing temperatures have been maintained until comparatively recent times.

6. Discussion

The zircon FT ages indicate that in all boreholes the level of the crust sampled in northern Switzerland never experienced temperatures in excess of $\sim 330^\circ\text{C}$ after the late Variscan consolidation of the crystalline basement, since total annealing of fission tracks in zircon is not observed. Zircon FT central ages and single-grain ages cluster at around 250 Ma and are substantially older than the central and single-grain ages from the nearby Black Forest (Fig. 14). The crystalline basement of northern Switzerland may be considered as the southern continuation of the internal zone of the Central European Variscides, now exposed in the Black Forest (e.g., Thury et al.

1994). The present-day outcrop level of the Black Forest approximately corresponds to the sampled depth range of the boreholes during Mesozoic subsidence. This can be stated because the Permo-Triassic paleosurface is partly preserved in the southern Black Forest (Paul 1955; Wimmenauer & Schreiner 1990). Primarily the Tertiary uplift of the Black Forest and the subsidence of the Alpine foreland, which was accompanied by reactivation of old fault zones in the study area (e.g., Müller et al. 2002), led to the current altitude difference between the two geographically neighbouring regions. Timar-Geng et al. (2004) interpreted the zircon FT data from the Black Forest in terms of a Jurassic heating event caused by regional-scale hydrothermal fluid migration. Obviously this thermal overprint is not observable from FT data in the borehole samples of northern Switzerland. Also, there is no other geological evidence for a main Jurassic hydrothermal phase in the crystalline basement of northern Switzerland. The youngest penetrative thermal event with a clear petrographic signature is a kaolinitic alteration and the formation of interconnected vugs in pre-existing structures with weakly constrained post-Permian ages (Mazurek et al. 1992) and authigenic illite formation in sandstones in the Jurassic (Schaltegger et al., 1995). Based on coalification and fission track data, Schegg & Leu (1998) estimated high palaeogeothermal gradients of 80–90 °C/km in northern Switzerland during the Late Palaeozoic. The zircon FT data of this study bear the signature of this regional thermal event, which also correlates with the rhyolitic volcanism known in the Black Forest. Common for both the Black Forest and the crystalline basement of northern Switzerland is the Cretaceous cooling below the zircon FT PAZ, i.e. below ~200 °C (e.g., Tagami & Shimada 1996; Tagami et al. 1998; see also discussion in Timar-Geng et al. 2004). This is inferred from the youngest single-grain age cluster dating the passage through the low-temperature boundary of the PAZ (Fügenschuh & Schmid 2003).

The apatite FT data document the low temperature (< ~120°C) thermal history of the region. The borehole samples mostly exhibit a trend of decreasing ages with depth (Fig. 3). This is a common feature in most geological settings and the shape of the age-depth graphs often reflects the thermal history of the rocks as they cooled through the PAZ (Gleadow & Brown 2000). Such age-depth profiles vary from nearly linear for high denudation rates to concave-upwards curves at low rates (Gleadow & Brown 2000). The age-depth trend of the Nagra borehole samples are approximated by a linear relationship, but a sound interpretation in terms of denudation rates is not recommended due to the measured track length distributions. In fact, thermal modelling of the FT data suggests a composite thermal history of the region with slow post-Eocene cooling and prolonged residence in the PAZ. The shape of the age-depth graph is, therefore, primarily controlled by the increase in temperature with depth and is not related to the denudation rate. There is a published apatite FT central age (160 ± 10 Ma; Mazurek et al. 2006) from the borehole Riniken from shallower depth, which is significantly

older than the Riniken samples in this study. Most probably this sample did not experience total annealing but rather also contains inherited tracks.

Modelling of the apatite FT parameters provides a fairly clear picture about the low-temperature thermal history of the crystalline basement of northern Switzerland since Cretaceous times (Figs. 10–13). All t-T paths (with the exception of Leu1 and Leu2) exhibit the same general shape: moderate to rapid Cretaceous cooling through the PAZ is followed by Eocene heating in-between the PAZ and subsequent cooling to present-day temperatures. The second cooling phase is characterised by prolonged residence in the PAZ. This is also implied by strongly reduced mean track lengths (Fig. 4) and scarcity of long tracks. The two lower Leuggern borehole samples (Leu1 and Leu2) apparently experienced total track loss during the Eocene heating event. Therefore, only the last cooling phase is documented by the apatite FT parameters. It should be stated that in spite of the excellent statistical goodness-of-fit values, the modelled thermal histories need not be unique. A broad range of t-T paths may generate FT parameters that could lie behind the measured data (Ketcham et al. 2000). Furthermore, cooling phases prior to reheating are not well documented by FT data for those temperatures lying below the maximum temperature of the reheating event due to annealing of all pre-existing tracks (De Bruijne & Andriessen 2002). The maximum temperature of a reheating event is quite well determined by modelling studies (Gleadow & Brown 2000). However, due to statistical uncertainties in the evaluation of the best-fit paths, the reconstruction of palaeogeothermal gradients based on modelling results is not recommended.

Some previous apatite FT modelling studies (Nagra 2002; Mazurek et al. 2006) dealt with parts of the Swiss Molasse Basin, located only a few km further to the south of the area presented here. Combined with other methods, Mazurek et al. (2006) reconstructed a multi-stage burial history of the basin with two successive stages of heating, one in the Cretaceous and the other in the Miocene. They relate the first heating episode to Mesozoic burial *and* an increased heat flux of 85–100 mW/m² in the Early Cretaceous. The second heating stage was caused by maximum burial during the Miocene (Mazurek et al. 2006). The initial cooling phase of our samples into the PAZ roughly coincides with the first cooling stage after Cretaceous burial and heating presented by Mazurek et al. (2006). Thus, it appears that the same Mesozoic thermal event caused total track annealing in the sampled crustal level of the external parts of northern Switzerland, mostly north of the Permo-Carboniferous trough. However, Cretaceous heating of the internal parts of northern Switzerland postdates the peak of the Mesozoic hydrothermal alteration observed in the neighbouring Black Forest, even though a less clear record of hydrothermal activity in the crystalline basement throughout the Cretaceous is also available (see compilation by Wetzel et al. 2003). Thus, in the case of the samples presented here, increased heat flux values affect the experienced total annealing of apatite fission tracks rather than burial below Mesozoic sediments.

Fig. 14. Frequency distribution of central ages (light grey) and single-grain ages (dark grey) for the Black Forest (Timar-Geng et al., 2004) and northern Switzerland (this study).

The striking feature of the modelled *t*-*T* paths of the present study is a major heating event of mostly Middle to Late Eocene age, which clearly predates the second heating stage in the Molasse basin. However, this can be explained by the tectonically and palaeogeographically different settings of the two regions. The borehole samples of this study are situated outside or in a marginal position of the Molasse basin, whereas the previously analysed samples (Mazurek et al. 2006) experienced substantial burial due to the subsidence of the Alpine foreland from the Late Oligocene onwards. Consequently, the elevated temperatures during the Miocene burial phase (e.g., Mazurek et al. 2006) might have overprinted a possible Eocene thermal pulse in the more internal parts of the Molasse basin. The Eocene heating event recorded in the FT data of this study, in contrast, can be related to the initial rifting stage of the nearby Upper Rhine Graben in the foreland of the evolving Alps (e.g., Schumacher 2002). This initial rifting stage was controlled by the gradually increasing subduction resistance of the European lithosphere and the build-up of intraplate stresses (Dèzes et al. 2004), and accompanied by progressively increasing volcanic activity (e.g., Lippolt 1983; Keller et al. 2002). Reactivation of Permo-Carboniferous crustal-scale fault systems played a fundamental role during the initial, Late Eocene rifting phase of the Upper Rhine Graben (Schumacher 2002) and was also characteristic for the entire foreland of the Alps at this time (Dèzes et al. 2004). Thus, faults of the Permo-Carboniferous Trough of northern Switzerland could have also acted as major conduits for circulating hydrothermal fluids giving rise to the observed middle to Late Eocene thermal event in the crystalline basement of northern Switzerland.

A distinctly accelerated cooling towards the present-day temperature, displayed by almost all modelled *t*-*T* paths, ap-

pears to be an artefact of the Laslett et al. (1987) algorithm (e.g. Ketcham et al. 2000) and, hence, is not further discussed.

7. Conclusions

The low-temperature thermal history of the crystalline basement of northern Switzerland has been derived by FT analysis on 17 borehole samples. Inverse modelling techniques were used to provide quantitative constraints on time-temperature histories that are in agreement with the measured data.

Within the investigated borehole sections, maximum palaeotemperatures never exceeded ~330 °C since post-Variscan peneplanation. Zircon FT central and single-grain ages do not show evidence for a Jurassic hydrothermal event, as was observed in the nearby southern Black Forest (Timar-Geng et al. 2004, 2006). Instead, the zircon FT data bear the signature of elevated Late Palaeozoic palaeogeothermal gradients (Schegg & Leu 1998).

Modelling results suggest that moderate to rapid cooling of the samples through the apatite PAZ at the end of the Mesozoic was followed by a distinct thermal event during the Eocene and subsequent slow cooling to present-day temperatures. For the duration of the second cooling phase the samples remained within the PAZ until comparatively recent times or even until present.

The Eocene heating event coincides with the initial rifting phases of the neighbouring Upper Rhine Graben and associated volcanic activity. It is proposed that faults of the Permo-Carboniferous Trough of northern Switzerland could have acted as important pathways for migrating hydrothermal fluids inducing the observed middle to Late Eocene thermal anomaly in the crystalline basement of northern Switzerland.

V. Summary and conclusions

by Zoltan Timar-Geng

The Upper Rhine Graben (URG) is part of a complex Cenozoic rift system that is located in the foreland of the Alps. The southern end of the URG is flanked by uplifted Variscan basement, exposed in the Black Forest and Vosges. The post-Variscan thermal evolution of the flanks of the southern URG and the neighbouring crystalline basement of northern Switzerland was evaluated by an extensive fission-track (FT) study.

The impact of the Jurassic hydrothermal activity on the interpretation of zircon FT data was elaborated by means of new zircon FT analyses on samples with known U/Pb crystallization ages (see Chapter II). FT central ages range from 162 Ma to 247 Ma. The analysed samples experienced substantial annealing prior to Cretaceous cooling that cannot be explained by burial alone. Instead, annealing is suggested to be associated with Jurassic hydrothermal activity, as also evidenced by vein mineralizations. Since samples entered the partial annealing zone (PAZ) from the lower temperature boundary and were only partially annealed, it can be presumed that a high density of α damage significantly lowered the thermal stability of the zircon fission tracks. Thus, it is suggested that circulating hydrothermal fluids with temperatures in the order of 200 – 250 °C were sufficient to give rise to the observed thermal anomaly. This has important implications for the interpretation of FT data in areas known as having been hydrothermally altered in the past. Analysis of FT data using simple assumptions such as a constant paleogeothermal gradient leads unavoidably to erroneous conclusions. Thus, interpretation of available FT ages from the Black Forest and Vosges as cooling ages is questionable. Particularly the gradients of age-elevation profiles do not correspond to input denudation rates.

FT ages of 28 outcrop samples collected along two E-W trending transects from the Black Forest and Vosges (Chapter III) cover the whole range of ages found by previous studies. Zircon FT central ages vary from 136 Ma to 312 Ma. Apatite FT ages range between 20 Ma and 83 Ma. Broad and/or bimodal track lengths distributions indicate a complex thermal history, which was determined by inverse modelling of FT parameters and tested against the observed dataset and independent geological constraints. It provided a comprehensive thermochronological record of the study area from the Lower Cretaceous to present, characterised by a compound cooling history with a transient heating event in the Upper Eocene. This heating phase is contemporaneous to the initial rifting stage of the URG and associated with increased volcanic activity.

One open question regarding the regional geology of the URG area is whether Cretaceous sediments were deposited and subsequently eroded completely or never existed. Interpreting the youngest cluster of zircon FT single-grain ages as dating the passage of a sample through the lower limit of the zircon FT PAZ, and interpolating the known Mesozoic sediment thicknesses from surrounding regions into the study area, it can be concluded that not even a significant

amount (kilometre-scale) of Upper Jurassic to Lower Cretaceous sedimentary sequence would have been sufficient to cause the observed very high paleotemperatures. Instead of cooling on account of tectonic uplift and denudation, the cessation of the Mesozoic hydrothermal activity is suggested as reason for the Cretaceous cooling below the lower limit of the zircon FT PAZ.

Based on modelling results and on a cautious estimation of the prevailing paleogeothermal gradient the total amount of denudation from the flanks of the URG since the Upper Eocene could be estimated. It amounts to 1.0 – 1.7 km for a paleogeothermal gradient of 60 °C/km and 1.3 to 2.2 km for a paleogeothermal gradient of 45 °C/km.

In addition to the samples from the Black Forest and Vosges, FT data from four boreholes, which penetrated the pre-Mesozoic basement of the neighbouring area of northern Switzerland, were also collected (Chapter IV). Zircon FT central ages and single-grain ages cluster around 250 Ma, thus it can be concluded that maximum palaeotemperatures did not exceed ~330 °C (i.e. temperatures for complete track loss) after late-Variscan consolidation of the crystalline basement. Apatite FT central ages range between 25 Ma and 87 Ma. Confined mean track lengths range between 9.3 µm and 11.6 µm suggesting substantial annealing of all samples. Inverse modelling techniques have been used to provide quantitative constraints on the low-temperature thermochronology of the area that are permitted by the measured data. The revealed thermal history is very similar to the one obtained for the southern URG area: Cretaceous cooling is followed by an Eocene heating event and subsequent cooling to present-day temperatures. Apparent differences to earlier FT modelling results can be explained by the different paleogeographic positions of the sample localities. The Eocene heating episode is contemporaneous to the initial rifting stage of the nearby URG. Reactivated crustal-scale faults of the Permo-Carboniferous Trough of northern Switzerland could have acted as major conduits for circulating hydrothermal fluids giving rise to the observed middle to late Eocene thermal anomaly.

In general it can be concluded that the southern URG was an area with repeatedly changing paleogeothermal gradients, and convective heat transport seems to have played an important role throughout its post-Variscan thermotectonic evolution. Thus, the available FT ages cannot be interpreted as cooling ages and no denudation rates based on age-elevation profiles can be derived. Only the thermal modelling approach can offer a meaningful interpretation of the existing dataset.

Appendix

Raw FT data

Appendix

In this appendix the raw FT data are presented, subdivided into three data sets according to the three main parts of the thesis.

1. Zircon FT data from the Black Forest and the Vosges with known crystallisation ages („SU“-Samples).

The interpretation of this data set is presented in Chapter II of the thesis.

CURRICULUM VITAE

Zoltan Timar-Geng

Personal details

Date of birth: 23.01.1973

Place of birth: Carei / Romania

Nationality: German

Working address:

Geological-Paleontological Institute

University of Basel

Bernoullistrasse 32

CH-4056 Basel

Private address:

Oberer Kirchweg 19

D-79112 Freiburg

E-mail: zoltan.timar-geng@unibas.ch

Studies

Aug. 2000 – Febr. 2005

PhD in Geology: „Post-Variscan thermal evolution of the flanks of the southern Upper Rhine Graben: fission-track analyses and thermal modelling.“

Oct. 1995 – July 2000

Studying Geology at the Albert-Ludwigs-Universität Freiburg.

„Diploma“ in Geology: „Strukturgeologische Untersuchungen im Leventina-Tal und kinematische Analyse von Quarztexturen aus dem Bereich der Deckengrenze zwischen Leventina- und Simano-Decke, Kanton Tessin, Schweiz“.

Practical training

March 1998 – April 1998

Hydro-Data, Ballrechten-Dottingen, Germany
Hydrogeological investigations.

June 1997 – July 1997

Terratec, Heitersheim, Germany
Geophysical services.
